Foreword

My first introduction to robotics came via a phone call in 1964. The caller was Fred Terman, the author of the world-famous *Radio Engineer's Handbook*, who was at the time Provost of Stanford University. Dr. Terman informed me that a computer science professor, John McCarthy, had just been awarded a large research grant, part of which required the development of computer-controlled manipulators. Someone had suggested to Terman that it would be prudent if the mathematically oriented McCarthy had some contact with mechanical designers. Since I was the only one on the Stanford faculty whose specialty was mechanism design, Terman decided to phone me, even though we had never met and I was a young assistant professor fresh out of graduate school with only 2 years at Stanford.

Dr. Terman's phone call led me to a close association with John McCarthy and the Stanford Artificial Intelligence Laboratory (SAIL) that he founded. Robotics became one of the pillars of my entire academic career, and I have maintained my interest in teaching and researching the subject through to the present day.

The modern history of robotic manipulation dates from the late 1940s when servoed arms were developed in connection with master-slave manipulator systems used to protect technicians handling nuclear materials. Developments in this area have continued to the present day. However, in the early 1960s there was very little academic or commercial activity in robotics. The first academic activity was the thesis of H. A. Ernst, in 1961, at MIT. He used a slave arm equipped with touch sensors, and ran it under computer control. The idea in his study was to use the information from the touch sensors to guide the arm.

This was followed by the SAIL project and a similar project started by Professor Marvin Minsky at MIT, which were the only sizeable academic ventures into robotics at that time. There were a few attempts at commercial manipulators, primarily in connection with part production in the automotive industry. In the USA there were two different manipulator designs that were being experimented with in the auto industry; one came from American Machine and Foundry (AMF) and the other from Unimation, Inc.

There were also a few mechanical devices developed as hand, leg, and arm prosthetics, and, a bit later, some exoskeletal devices to enhance human performance. In those days there were no microprocessors. So, these devices were either without computer control,

or tethered to a remote so-called minicomputer, or even a mainframe computer.

Initially, some in the computer science community felt that computers were powerful enough to control any mechanical device and make it perform satisfactorily. We quickly learned that this was not to be the case. We started on a twofold track. One was to develop particular devices for SAIL, so that hardware demonstrations and proof-of-concept systems were available for the fledgling robotics community to experiment with. The other track, which was more or less moonlighted from the work at SAIL, was the development of a basic mechanical science of robotics. I had a strong feeling that a meaningful science could be developed, and that it would be best to think in terms of general concepts rather than concentrate exclusively on particular devices.

Fortuitously, it turned out that the two tracks supported each other very naturally and, most importantly, the right students were interested in doing their research in this area. Hardware developments proved to be specific examples of more general concepts, and the students were able to develop both the hardware and the theory.

Originally, we purchased an arm in order to get started quickly. A group at Rancho Los Amigos Hospital, in Los Angeles, was selling a tongue-switch-controlled motor-driven exoskeleton arm to assist patients without muscular control of their arms. We purchased one of these, and connected it to a time-shared PDP-6 computer. The device was named *Butterfingers*; it was our first experimental robot. Several films demonstrating visual feedback control, block stacking tasks, and obstacle avoidance were made with *Butterfingers* as the star performer.

The first manipulator that we designed on our own was known simply as the *Hydraulic Arm*. As its name implies, it was powered by hydraulics. The idea was to build a very fast arm. We designed special rotary actuators, and the arm worked well. It became the experimental platform for testing the first ever dynamic analysis and time-optimal control of a robotic arm. However, its use was limited since the design speeds were much faster than required due to the limitations

Bernard Roth
Professor of
Mechanical Engineering
Stanford University

of the computational, planning, and sensing capabilities that were common at that time.

We made an attempt to develop a truly digital arm. This led to a snake-like structure named the *Orm* (the Norwegian word for snake.) The *Orm* had several stages, each with an array of inflatable pneumatic actuators that were either fully extended or fully contracted. The basic idea was that, even though only a finite number of positions in the workspace could be reached, these would be sufficient if there were a large number of positions. A small prototype proof-of-concept *Orm* was developed. It led to the realization that this type of arm would not really serve the SAIL community.

The first truly functional arm from our group was designed by Victor Scheinman, who was a graduate student at the time. It was the very successful *Stanford Arm*, of which over ten copies were made as research tools to be used in various university, government, and industrial laboratories. The arm had six independently driven joints; all driven by computer-controlled servoed, DC electric motors. One joint was telescoping (prismatic) and the other five were rotary (revolute).

Whereas the geometry of *Butterfingers* required an iterative solution of the inverse kinematics, the geometric configuration of the *Stanford Arm* was chosen so that the inverse kinematics could be programmed in any easy-to-use time-efficient closed form. Furthermore, the mechanical design was specifically made to be compatible with the limitations inherent in time-share computer control. Various end-effectors could be attached to act as hands. On our version, the hand was in the form of a vise-grip jaw, with two sliding fingers driven by a servoed actuator (hence, a true seventh degree of freedom). It also had a specially designed six-axis wrist force sensor. Victor Scheinman went on to develop other important robots: the first was a small humanoid arm with six revolute joints. The original design was paid for by Marvin Minsky at the MIT AI Lab. Scheinman founded Vicarm, a small company, and produced copies of this arm and the *Stanford Arm* for other labs. Vicarm later became the West Coast Division of Unimation, Inc., where Scheinman designed the *PUMA* manipulator under General Motors sponsorship through Unimation. Later, for a company called Automatix, Scheinman developed the novel *Robot World* multirobot system. After Scheinman left Unimation, his colleagues Brian Carlisle and Bruce Shimano reorganized Unimation's West Coast Division into Adept, Inc., which to this day is the largest US manufacturer of assembly robots.

Quickly, the modern trend of carefully detailed mechanical and electronic design, optimized software, and

complete system integration became the norm; to this day, this combination represents the hallmark of most highly regarded robotic devices. This is the basic concept behind *mechatronic*, a word coined in Japan as a concatenation of the words mechanics and electronics. Mechatronics that relies on computation is the essence of the technology inherent in robotics as we know it today.

As robotics developed around the world, a large number of people started working on various aspects, and specific subspecialties developed. The first big division was between people working on manipulators and those working on vision systems. Early on, vision systems seemed to hold more promise than any other method for giving robots information about their environment.

The idea was to have a television camera capture pictures of objects in the environment, and then use algorithms that allowed the computer images of the pictures to be analyzed, so as to infer required information about location, orientation, and other properties of objects. The initial successes with image systems were in problems dealing with positioning blocks, solving object manipulation problems, and reading assembly drawings. It was felt that vision held potential for use in robotic systems in connection with factory automation and space exploration. This led to research into software that would allow vision systems to recognize machine parts (particularly partially occluded parts, as occurred in the so-called *bin-picking* problems) and ragged-shaped rocks.

After the ability to *see* and move objects became established, the next logical need had to do with planning a sequence of events to accomplish a complex task. This led to the development of planning as an important branch in robotics. Making fixed plans for a known fixed environment is relatively straightforward. However, in robotics, one of the challenges is to let the robot discover its environment, and to modify its actions when the environment changes unexpectedly due to errors or unplanned events. Some early landmark studies in this area were carried out using a vehicle named *Shakey*, which, starting in 1966, was developed by Charlie Rosen's group at the Stanford Research Institute (now called SRI). *Shakey* had a TV camera, a triangulating range finder, bump sensors, and was connected to DEC PDP-10 and PDP-15 computers via radio and video links.

Shakey was the first mobile robot to reason about its actions. It used programs that gave it the ability for independent perception, world modeling, and action generation. Low-level action routines took care of simple moving, turning, and route planning. Intermediate-

level actions combined the low-level ones in ways that accomplished more complex tasks. The highest level programs could make and execute plans to achieve high-level goals supplied by a user.

Vision is very useful for navigation, locating objects, and determining their relative positions and orientation. However, it is usually not sufficient for assembling parts or working with robots where there are environmental constraining forces. This led to the need to measure the forces and torques generated by the environment, on a robot, and to use these measurements to control the robot's actions. For many years, force-controlled manipulation became one of the main topics of study at SAIL, and several other labs around the world. The use of force control in industrial practice has always lagged the research developments in this area. This seems to be due to the fact that, while a high level of force control is very useful for general manipulation issues, specific problems in very restricted industrial environments can often be handled with limited, or no, force control.

In the 1970s, specialized areas of study such as walking machines, hands, automated vehicles, sensor integration, and design for hostile environments began to develop rapidly. Today there are a large number of different specialties studied under the heading of robotics. Some of these specialties are classical engineering subject areas within which results have been developed that have been particularized to the types of machines called robots. Examples here are kinematics, dynamics, controls, machine design, topology, and trajectory planning. Each of these subjects has a long history predating the study of robotics; yet each has been an area of in-depth robotics research in order to develop its special character in regard to robotic-type systems and applications. In doing this specialized development, researchers have enriched the classical subjects by increasing both their content and scope.

At the same time that the theory was being developed, there was a parallel, although somewhat separate, growth of industrial robotics. Strong commercial development occurred in Japan and Europe, and there was also continued growth in the USA. Industrial associations were formed (the Japan Robot Association was formed in March 1971, and the Robotic Industries Association (RIA) was founded in 1974 in the USA) and trade shows, together with application-oriented technical sessions, were introduced and held on a regular basis. The most important were the International Symposium on Industrial Robots, the Conference on Industrial Robot Technology (now called the International Conference on Industrial Robot Technology), and the

RIA annual trade show, which is now called the International Robots and Vision Show and Conference.

The first regular series of conferences emphasizing research, rather than the industrial, aspects of robotics, was inaugurated in 1973. It was sponsored jointly by the International Center for Mechanical Sciences (CISM), based in Udine, Italy, and the International Federation for the Theory of Mechanisms and Machines (IFTToMM). (Although IFTToMM is still used, its meaning has been changed to the International Federation for the Promotion of Mechanism and Machine Science.) It was named the Symposium on Theory and Practice of Robots and Manipulators (RoManSy). Its trademark was an emphasis on the mechanical sciences and the active participation of researchers from Eastern and Western Europe as well as North America and Japan. It is still held biannually. On a personal note, it is at RoManSy where I first met each of the editors of this Handbook: Dr. Khatib in 1978 and Dr. Siciliano in 1984. They were both students: Bruno Siciliano had been working on his PhD for about one year, and Oussama Khatib had just completed his PhD research. In both cases, it was love at first sight!

RoManSy was quickly joined by a host of other new conferences and workshops; today there are a large number of research oriented robotics meetings that take place through the year in many countries. Currently, the largest conference is the International Conference on Robotics and Automation (ICRA), which regularly draws well over 1000 participants.

In the beginning of the 1980s, the first real textbook on robotic manipulation in the USA was written by Richard Lou Paul (Richard P. Paul, *Robot Manipulators: Mathematics, Programming, and Control*, The MIT Press, Cambridge, MA, 1981). It used the idea of taking classical subjects in mechanics and applying them to robotics. In addition there were several topics developed directly from his thesis research at SAIL. (In the book, many examples are based on Scheinman's Stanford Arm.) Paul's book was a landmark event in the USA; it created a pattern for several influential future textbooks and also encouraged the creation of specialized robotics courses at a host of colleges and universities.

At about this same time, new journals were created to deal primarily with research papers in the areas related to robotics. The *International Journal of Robotics Research* was founded in the spring of 1982, and three years later the *IEEE Journal of Robotics and Automation* (now the *IEEE Transactions on Robotics*) was founded.

As microprocessors became ubiquitous, the question of what is or is not a robot came more into

play. This issue has, in my mind, never been successfully resolved. I do not think a definition will ever be universally agreed upon. There are of course the science fiction creatures-from-outer-space varieties, and the robots of the theater, literature, and the movies. There are examples of imaginary robot-like beings that predate the industrial revolution, but how about more down-to-Earth robots? In my view the definition is essentially a moving target that changes its character with technological progress. For example, when it was first developed, a ship's gyro auto-compass was considered a robot. Today, it is not generally included when we list the robots in our world. It has been demoted and is now considered an automatic control device.

For many, the idea of a robot includes the concept of multifunctionality, meaning the device is designed and built with the ability to be easily adapted or re-programmed to do different tasks. In theory this idea is valid, but in practice it turns out that most robotic devices are multifunctional in only a very limited arena. In industry it was quickly discovered that a specialized machine, in general, performs much better than a general purpose machine. Furthermore, when the volume of production is high enough, a specialized machine can cost less to manufacture than a generalized one. So, specialized robots were developed for painting, riveting, quasiplanar parts assembly, press loading, circuit board stuffing, etc. In some cases robots are used in such specialized ways that it becomes difficult to draw the line between a so-called robot and an adjustable piece of *fixed* automation. Much of this practical unfolding is contrary to the dream of the pioneers in robotics, who had hoped for the development of general purpose machines that would do *everything*, and hence sell in great enough volume to be relatively inexpensive.

My view is that the notion of a robot has to do with which activities are, at a given time, associated with people and which are associated with machines. If a machine suddenly becomes able to do what we normally associate with people, the machine can be upgraded in classification and classified as a robot. After a while, people get used to the activity being done by machines, and the devices get downgraded from *robot* to *machine*. Machines that do not have fixed bases, and those that have arm- or leg-like appendages have the advantage of being more likely called robots, but it is hard to think of a consistent set of criteria that fits all the current naming conventions.

In actuality any machines, including familiar household appliances, which have microprocessors directing their actions can be considered as robots. In addition to vacuum cleaners, there are washing machines, refrigerators, and dishwashers that could be easily marketed as robotic devices. There are of course a wide range

of possibilities, including those machines that have sensory environmental feedback and decision-making capabilities. In actual practice, in devices considered to be robotic, the amount of sensory and decision making capability may vary from a great deal to none.

In recent decades the study of robotics has expanded from a discipline centered on the study of mechatronic devices to a much broader interdisciplinary subject. An example of this is the area called human-centered robotics. Here one deals with the interactions between humans and intelligent machines. This is a growing area where the study of the interactions between robots and humans has enlisted expertise from outside the classical robotics domain. Concepts such as emotions in both robots and people are being studied, and older areas such as human physiology and biology are being incorporated into the mainstream of robotics research. These activities enrich the field of robotics, as they introduce new engineering and science dimensions into the research discourse.

Originally, the nascent robotics community was focused on getting things to work. Many early devices were remarkable in that they worked at all, and little notice was taken of their limited performance. Today, we have sophisticated, reliable devices as part of the modern array of robotic systems. This progress is the result of the work of thousands of people throughout the world. A lot of this work took place in universities, government research laboratories, and companies. It is a tribute to the worldwide engineering and scientific community that it has been able to create the vast amount of information that is contained in the 64 chapters of this Handbook. Clearly these results did not arise by any central planning or by an overall orderly scheme. So the editors of this handbook were faced with the difficult task of organizing the material into a logical and coherent whole.

The editors have accomplished this by organizing the contributions into a three-layer structure. The first layer deals with the *foundations* of the subject. This layer consists of a single part of nine chapters in which the authors lay out the root subjects: kinematics, dynamics, control, mechanisms, architecture, programming, reasoning, and sensing. These are the basic technological building blocks for robotics study and development.

The second layer has four parts. The first of these deals with *robot structures*; these are the arms, legs, hands, and other parts that most robots are made up of. At first blush, the hardware of legs, arms, and hands may look quite different from each other, yet they share a common set of attributes that allows them to all be treated with the same, or closely related, aspects of the fundamentals described in the first layer.

The second part of this layer deals with *sensing and perception*, which are basic abilities any truly autonomous robotic system must have. As was pointed out earlier, in practice, many so-called robotic devices have little of these abilities, but clearly the more advanced robots cannot exist without them, and the trend is very much toward incorporating such capabilities into robotic devices. The third part of this layer treats the subject areas associated with the technology of *manipulation and the interfacing of devices*. The fourth part of this layer is made up of eight chapters that treat *mobile robots and various forms of distributed robotics*.

The third layer consists of two separate parts (a total of 22 chapters) that deal with advanced applications at the forefront of today's research and development. There are two parts to this layer; one deals with *field and service robots*, and the other deals with *human-centered and lifelike robots*. To the uninitiated observer, these chapters are what advanced robotics is all about. However, it is important to realize that many of these

extraordinary accomplishments would probably not exist without the previous developments introduced in the first two layers of this Handbook.

It is this intimate connection between theory and practice that has nurtured the growth of robotics and become a hallmark of modern robotics. These two complementary aspects have been a source of great personal satisfaction to those of us who have had the opportunity to both research and develop robotic devices. The contents of this Handbook admirably reflect this complementary aspect of the subject, and present a very useful bringing together of the vast accomplishments which have taken place in the last 50 years. Certainly, the contents of this Handbook will serve as a valuable tool and guide to those who will produce the even more capable and diverse next generations of robotic devices. The editors and authors have my congratulations and admiration.

Stanford, August 2007

Bernard Roth

Foreword

To open this Handbook and unfold the richness of its 64 chapters, we here attempt a brief personal overview to sketch the evolution of robotics in its many aspects, concepts, trends, and central issues.

The modern story of Robotics began about half a century ago with developments in two different directions.

First, let us acknowledge the domain of mechanical arms, ranging from teleoperated tasks on radiation-contaminated products to industrial arms, with the landmark machine UNIMATE – standing for uni(versal)mate. The industrial development of products, mostly around the six-degree-of-freedom serial links paradigm and active research and development, associating mechanical engineering to the control specialism, was the main driving force here. Of particular note nowadays is the successfully pursued effort to design novel application-optimized structures, using powerful sophisticated mathematical tools. In a similar way, an important issue concerns the design and the actual building of arms and hands in the context of human-friendly robots for tomorrow's cognitive robot.

Second, and less well recognized, we should acknowledge the stream of work concerned with themes in artificial intelligence. A landmark project in this area was the mobile robot *Shakey* developed at Stanford International. This work, which aimed to bring together computer science, artificial intelligence, and applied mathematics to develop intelligent machines, remained a secondary area for quite some time. During the 1980s, building strength from many study cases encompassing a spectacular spectrum ranging from rovers for extreme environments (planet exploration, Antarctica, etc.), to service robots (hospitals, museum guides, etc.), a broad research domain arose in which machines could claim the status of intelligent robots.

Hence robotics researches could bring together these two different branches, with intelligent robots categorized in a solely computational way as bounded rationality machines, expanding on the 1980s third-generation robot definition:

(robot) . . . operating in the three-dimensional world as a machine endowed with the capacity to interpret and to reason about a task and about its execution, by intelligently relating perception to action.

The field of autonomous robots, a widely recognized test-bed, has recently benefited from salient contributions in robot planning using the results of

algorithmic geometry as well as of a stochastic framework approach applied both to environmental modeling and robot localization problems (SLAM, simultaneous localization and modeling), and further from the development of decisional procedures via Bayesian estimation and decision approaches.

For the last decade of the millennium, robotics largely dealt with the intelligent robot paradigm, blending together robots and machine-intelligence generic research within themes covering advanced sensing and perception, task reasoning and planning, operational and decisional autonomy, functional integration architectures, intelligent human-machine interfaces, safety, and dependability.

The second branch, for years referred to as non-manufacturing robotics, concerns a wide spectrum of research-driven real-world cases pertaining to field, service, assistive, and, later, personal robotics. Here, machine intelligence is, in its various themes, the central research direction, enabling the robot to act:

1. As a human surrogate, in particular for intervention tasks in remote and/or hostile environments
2. In close interaction with humans and operating in human environments in all applications encompassed by human-friendly robotics, also referred to as human-centered robotics
3. In tight synergy with the user, expanding from mechanical exoskeleton assistance, surgery, health care, and rehabilitation into human augmentation.

Consequently, at the turn of the millennium, robotics appears as a broad spectrum of research themes both supporting market products for well-engineered industrial workplaces, and a large number of domain-oriented application cases operating in hazardous and/or harsh environments (underwater robotics, rough-terrain rovers, health/rehabilitation care robotics, etc.) where robots exhibit meaningful levels of shared autonomy.

The evolution levels for robotics stress the role of theoretical aspects, moving from application domains to the technical and scientific area. The organization of this Handbook illustrates very well these different lev-

Georges Giralt
Emeritus Research
Director
LAAS-CNRS Toulouse
(deceased)

els. Furthermore, it rightly considers, besides a body of software systems, front-line matters on physical appearance and novel appendages, including legs, arms, and hands design in the context of human-friendly robots for tomorrow's cognitive robot.

Forefront robotics in the first decade of the current millennium is making outstanding progress, compounding the strength of two general directions:

- Short/mid-term application-oriented study cases
- Mid/long-term generic situated research.

For completeness, we should mention the large number of peripheral, robotics-inspired subjects, quite often concerning entertainment, advertising, and sophisticated toys.

The salient field of human-friendly robotics encompasses several front-line application domains where the robots operate in a human environment and in close interaction with humans (entertainment and education, public-oriented services, assistive and personal robots, etc.), which introduces the critical issue of human-robot interaction.

Right at the core of the field, emerges the forefront topic of personal robots for which three general characteristics should be emphasized:

1. They may be operated by a nonprofessional user;
2. They may be designed to share high-level decision making with the human user;
3. They may include a link to environment devices and machine appendages, remote systems, and operators; the shared decisional autonomy concept (co-autonomy) implied here unfolds into a large set of cutting-edge research issues and ethical problems.

The concept of the personal robot, expanding to robot assistant and universal companion, is a truly great challenge for robotics as a scientific and technical field, offering the mid/long-term perspective of achieving a paramount societal and economical impact. This introduces, and questions, front-line topics encompassing cognitive aspects: user-tunable human-machine intel-

ligent interfaces, perception (scene analysis, category identification), open-ended learning (understanding the universe of action), skills acquisition, extensive robot-world data processing, decisional autonomy, and dependability (safety, reliability, communication, and operating robustness).

There is an obvious synergistic effort between the two aforementioned approaches, in spite of the necessary framework time differences. The scientific link not only brings together the problems and obtained results but also creates a synergistic exchange between the two sides and the benefits of technological progress.

Indeed, the corresponding research trends and application developments are supported by an explosive evolution of enabling technologies: computer processing power, telecommunications, networking, sensing devices, knowledge retrieval, new materials, micro- and nanotechnologies.

Today, looking to the mid- and long-term future, we are faced with very positive issues and perspectives but also having to respond to critical comments and looming dangers for machines that are in physical contact with the user and may also be capable of unwanted, unsafe behavior. Therefore, there is a clear need to include at the research level safety issues and the topic of multifaced dependability and the corresponding system constraints.

The *Handbook of Robotics* is an ambitious and timely endeavor. It summarizes a large number of problems, questions, and facets considered by 164 authors in 64 chapters. As such it not only provides an efficient display of basic topics and results obtained by researches around the world, but furthermore gives access to this variety of viewpoints and approaches to everyone. This is indeed an important tool for progress but, much more, is the central factor that will establish the two first decades of this millennium as the dawn of robotics, lifted to a scientific discipline at the core of machine intelligence.

Toulouse, December 2007

Georges Giralt

Foreword

The field of robotics was born in the middle of the last century when emerging computers were altering every field of science and engineering. Having gone through fast yet steady growth via a procession of stages from infancy, childhood, and adolescence to adulthood, robotics is now mature and is expected to enhance the quality of people's lives in society in the future.

In its infancy, the core of robotics consisted of pattern recognition, automatic control, and artificial intelligence. Taking on these new challenge, scientists and engineers in these fields gathered to investigate novel robotic sensors and actuators, planning and programming algorithms, and architectures to connect these components intelligently. In so doing, they created artifacts that could interact with humans in the real world. An integration of these early robotics studies yielded *hand-eye systems*, the test-bed of artificial intelligence research.

The playground for childhood robotics was the factory floor. Industrial robots were invented and introduced into the factory for automating spraying, spot welding, grinding, materials handling, and parts assembly. Machines with sensors and memories made the factory floor smarter, and its operations more flexible, reliable, and precise. Such robotic automation freed humans from heavy and tedious labor. The automobile, electric appliance, and semiconductor industries rapidly retooled their manufacturing lines into robot-integrated systems. In the late 1970s, the word *mechatronics*, originally coined by the Japanese, defined a new concept of machinery, one in which electronics was fused with mechanical systems, making a wide range of industrial products simpler, more functional, programmable, and intelligent. Robotics and mechatronics exerted an evolutionary impact on the design and operation of manufacturing processes as well as on manufactured products.

As robotics entered its adolescence, researchers were ambitious to explore new horizons. Kinematics, dynamics, and control system theory were refined and applied to real complex robot mechanisms. To plan and carry out real tasks, robots had to be made cognizant of their surroundings. Vision, the primary channel for external sensing, was exploited as the most general, effective, and efficient means for robots to understand their external situation. Advanced algorithms and powerful devices were developed to improve the speed and robustness of robot vision systems. Tactile and force sensing systems also needed to be developed for

robots to manipulate objects. Studies on modeling, planning, knowledge, reasoning, and memorization expanded their intelligent properties. Robotics became defined as the study of intelligent connection of sensing to actuation. This definition covered all aspects of robotics: three scientific cores and one synthetic approach to integrate them. Indeed, system integration became a key aspect of robotic engineering as it allows the creation of lifelike machines. The fun of creating such robots attracted many students to the robotics field.

Hirochika Inoue
Professor Emeritus
The University of Tokyo

In advancing robotics further, scientific interest was directed at understanding humans. Comparative studies of humans and robots led to new approaches in scientific modeling of human functions. Cognitive robotics, lifelike behavior, biologically inspired robots, and a psychophysiological approach to robotic machines culminated in expanding the horizons of robotic potential. Generally speaking, an immature field is sparse in scientific understanding. Robotics in the 1980s and 1990s was in such a youthful stage, attracting a great many inquisitive researchers to this new frontier. Their continuous explorations into new realms form the rich scientific contents of this comprehensive volume.

Further challenges, along with expertise acquired on the cutting edge of robotics, opened the way to real-world applications for mature robotics. The early-stage playground gave way to a workshop for industrial robotics. Medical robotics, robot surgery, and in vivo imaging save patients from pain while providing doctors with powerful tools for conducting operations. New robots in such areas as rehabilitation, health care, and welfare are expected to improve quality of life in an aging society. It is the destiny of robots to go everywhere, in the air, under water, and into space. They are expected to work hand in hand with humans in such areas as agriculture, forestry, mining, construction, and hazardous environments and rescue operations, and to find utility both in domestic work and in providing services in shops, stores, restaurants, and hospitals. In a myriad of ways, robotic devices are expected to support our daily lives. At this point, however, robot applications are largely limited to structured environments, where they are separated from humans for safety sake.

In the next stage, their environment will be expanded to an unstructured world, one in which humans, as service takers, will always live and work beside robots. Improved sensing, more intelligence, enhanced safety, and better human understanding will be needed to prepare robots to function in such an environment. Not only technical but also social matters must be considered in finding solutions to issues impeding this progress.

Since my initial research to make a robot turn a crank, four decades have passed. I feel both lucky and happy to have witnessed the growth of robotics from its early beginnings. To give birth to robotics, fundamental technologies were imported from other disciplines. Neither textbooks nor handbooks were available. To reach the present stage, a great many scientists and engineers have challenged new frontiers; advancing robotics, they have enriched this body of knowledge from a variety of perspectives. The fruits of their endeavors are compiled in this *Handbook of Robotics*. More than 100 of the world's leading experts have collaborated in producing this publication. Now, people who wish to commit themselves to robotics research can find a firm founda-

tion to build upon. This Handbook is sure to be used to further advance robotics science, reinforce engineering education, and systematically compile knowledge that will innovate both society and industry.

The roles of humans and robots in an aging society pose an important issue for scientists and engineers to consider. Can robotics contribute to securing peace, prosperity, and a greater quality of life? This is still an open question. However, recent advances in personal robots, robotic home appliances, and humanoids suggest a paradigm shift from the industrial to the service sector. To realize this, robotics must be addressed from such viewpoints as the working infrastructure within society, psychophysiology, law, economy, insurance, ethics, art, design, drama, and sports science. Future robotics should be studied as a subject that envelops both humanity and technology. This Handbook offers a selected technical foundation upon which to advance such newly emerging fields of robotics. I look forward to continuing progress adding page after page of robot-based prosperity to future society.

Tokyo, September 2007

Hirochika Inoue

Foreword

Robots have fascinated people for thousands of years. Those automatons that were built before the 20th century did not connect sensing to action but rather operated through human agency or as repetitive machines. However, by the 1920s electronics had gotten to the stage that the first true robots that sensed the world and acted in it appropriately could be built. By 1950 we started to see descriptions of real robots appearing in popular magazines. By the 1960s industrial robots came onto the scene. Commercial pressures made them less and less responsive to their environments but faster and faster in what they did in their carefully engineered world. Then in the mid 1970s in France, Japan, and the USA we started to see robots rising again in a handful of research laboratories, and now we have arrived at a world-wide frenzy in research and the beginnings of large-scale deployment of intelligent robots throughout our world. This Handbook brings together the current state of robotics research in one place. It ranges from the mechanism of robots through sensing and perceptual processing, intelligence, action, and many application areas.

I have been more than fortunate to have lived with this revolution in robotics research over the last 30 years. As a teenager in Australia I built robots inspired by the tortoises of Walter described in the *Scientific American* in 1949 and 1950. When I arrived in Silicon Valley in 1977, just as the revolution in the personalization of computation was really coming into being, I instead turned to the much more obscure world of robots. In 1979 I was able to assist Hans Moravec at the Stanford Artificial Intelligence Lab (SAIL) as he coaxed his robot *The Cart* to navigate 20 m in 6 hours. Just 26 years later, in 2005, at the same laboratory, SAIL, Sebastian Thrun and his team coaxed their robot to autonomously drive 200 000 m in 6 hours: four orders of magnitude improvement in a mere 26 years, which is slightly better than a doubling every 2 years. However, robots have not just improved in speed, they have also increased in number. When I arrived at SAIL in 1977 we knew of three mobile robots operating in the world. Recently a company that I founded manufactured its 3 000 000th mobile robot, and the pace is increasing. Other aspects of robots have had similarly spectacular advances, although it is harder to provide such crisp numeric characterizations. In recent years we have gone from robots being too unaware of their surroundings that it was unsafe for people to share their workspace to robots that people can work with in close

contact, and from robots that were totally unaware of people to robots that pick up on natural social cues from facial expressions to prosody in people's voices. Recently robotics has crossed the divide between flesh and machines so that now we are seeing neurorobotics ranging from prosthetic robotic extensions to rehabilitative robots for the disabled. And very recently robotics has become a respected contributor to research in cognitive science and neuroscience.

The research results chronicled in this volume give the key ideas that have enabled these spectacular advances. The editors, the part editors, and all the contributors have done a stellar job in bring this knowledge together in one place. Their efforts have produced a work that will provide a basis for much further research and development. Thank you, and congratulations to all who have labored on this pivotal book.

Some of the future robotics research will be incremental in nature, taking the state of the art and improving upon it. Other parts of future research will be more revolutionary, based on ideas that are antithetical to some of the ideas and current state of the art presented in this book.

As you study this volume and look for places to contribute to research through your own talents and hard work I want to alert you to capabilities or aspirations that I believe will make robots even more useful, more productive, and more accepted. I describe these capabilities in terms of the age at which a child has equivalent capabilities:

- The object-recognition capabilities of a 2-year-old child
- The language capabilities of a 4-year-old child
- The manual dexterity of a 6-year-old child
- The social understanding of an 8-year-old child.

Each of these is a very difficult goal. However even small amounts of progress towards any one of these goals will have immediate applications to robots out in the world. Good reading and best wishes as you contribute further to robotkind.

Preface to the Second Edition

The Springer Handbook of Robotics was a challenging six-year endeavour from 2002 to 2008. It mobilized a large number of active scientists and researchers to produce this unique comprehensive reference source combining basic and advanced developments. The handbook has been very successful and extremely well received in our community. New researchers have been attracted to robotics which in turn have contributed to further progress in this trans-disciplinary field.

The handbook soon established itself as a landmark in robotics publishing and beyond. It has been the bestseller of all Springer engineering books during the last seven years, the number one in chapter downloads (nearly forty thousand a year), and the fourth most downloaded over all Springer books in 2011. In February 2009, the handbook was recognized as the Winner of the American Association of Publishers (AAP) PROSE Award for Excellence in Physical Sciences & Mathematics as well as the Award for Engineering & Technology.

The rapid growth of our field as well as the birth of new research areas motivated us in 2011 to start pursuing a second edition with the intent to provide not only an update but also an expansion of the handbook's contents. Our editorial board (with David Orin, Frank Park, Henrik Christensen, Makoto Kaneko, Raja Chatila, Alex Zelinsky, and Daniela Rus) has been enthusiastically engaged during the last four years to coordinate the contributions of the authors to the seven parts of the handbook in its three-layer structure. The contents have been restructured to achieve four main objectives: the enlargement of foundational topics for robotics, the enlightenment of design of various types of robotic systems, the extension of the treatment on robots moving in the environment, and the enrichment of advanced robotics applications. Most previous chapters have been revised, fifteen new chapters have been introduced on emerging topics, and a new generation of authors have joined the handbook's team. The contents were finalized by the spring of 2015 after extensive review and feedback, and the project was completed by the fall of 2015 – generating, by that time, a record of over 12 000 additional emails in our folders to the 10 000 of the first edition. The result is an impressive collection of 80 chapters over the 7 parts, contributed by 229 authors,

with more than 2300 pages, 1375 illustrations and 9411 references.

One of the major additions of the second edition of the handbook is the inclusion of multimedia material. An editorial team has been established under the leadership of Torsten Kröger and the contributions of Gianluca Antonelli, Dongjun Lee, Dezhen Song and Stefano Stramigioli. With the commitment of such a group of energetic young scholars, the multimedia project has been pursued in parallel to the handbook project. The multimedia editorial team has selected for each chapter video contributions, from those suggested by the authors, based on their quality and relevance to the chapter's contents. In addition, the handbook editors have produced tutorial videos that can be accessed directly from each part of the handbook. An openly accessible multimedia website, <http://handbookofrobotics.org>, has been established to host these videos with the sponsorship of IEEE Robotics and Automation Society and Google. The website has been conceived as a live dissemination project bringing the latest robotics contributions to the world community.

We are deeply grateful for the continuous commitment of our handbook extended team, particularly the newcomers to the project. We would like to express our gratitude and appreciation to Judith Hinterberg, Werner Skolaut and Thomas Ditzinger from Springer for their strong support, as well as to Anne Strohbach and the le-tex staff for their highly professional typesetting work in the production.

Eight years after the first appearance of the handbook, the second edition comes to light. Beyond its tutorial value for our community, it is our conviction that the handbook will continue to serve as a useful source to attract new researchers to robotics and inspire decades of vibrant progress in this fascinating field. The cooperative spirit inspiring our team since the inception of the first edition is amusingly illustrated in the video *The Handbook – A Short History* ( VIDEO 844). The completion of the second edition has been inspired by that same spirit and the gradient has been kept :-). Our fellows in the robotics community are reminded now to ... keep the Hessian :-)

Preface to the Multimedia Extension

Scientific and technical advancements in the domain of robotics have accelerated significantly over the past decade. Since the inception of the Second Edition of the Springer Handbook of Robotics in 2011, the Editors Bruno Siciliano and Oussama Khatib decided to add multimedia content and appointed an editorial team: Gianluca Antonelli, Dongjun Lee, Dezheng Song, Stefano Stramigioli, and myself as the Multimedia Editor.

Over the five years of the project, everyone on the team worked with all of the 229 authors, the Part Editors, and the Editors. Besides communicating with all 80 Authors' teams and reviewing, selecting, and improving all video contributions, we also scanned all the videos published at robotics conferences organized by the IEEE Robotics and Automation Society since 1991. A total of more than 5500 e-mails were sent back and forth to coordinate the project and to ensure the quality of the content. We implemented a video management system that allows authors to upload videos, editors to review videos, and readers to access videos. Videos were selected with the goal of helping convey content to all readers of the Second Edition. They may be relevant from a technical, scientific, educational, or historical perspective. All chapter and part videos are publicly accessible and can be found at

<http://handbookofrobotics.org>

In addition to the videos referenced in the chapters, each of the seven parts is accompanied by a part video giving an overview of each part. The storyboards of these videos were created by the Part Editors and then professionally produced.

The video content provided in the Multimedia Extension makes understanding the written content easier and was designed to be a comprehensive addition to the Handbook. Concepts, methods, experiments, and applications described in the book were animated, visually illustrated, or paired with sound and narration – giving readers a further dimension to comprehend the written content of the book.

Coordinating the work with more than 200 contributors cannot just be done by a small team, and we are deeply grateful for the support of many people and organizations. Judith Hinterberg and Thomas Ditzinger from the Springer Team in Heidelberg helped us tremendously with professional support during the entire production phase. The app for smartphones and tablets was implemented by Rob Baldwin from Studio Orb and allows readers easy access to multimedia content. The IEEE Robotics and Automation Society granted permissions to use all videos that have been published in the proceedings of conferences sponsored by the society. Google and X supported us by donating funds for the implementation of the website backend.

Following the Editors' inspiration, let us keep working and communicating as one community – and let us keep the Hessian all together ... !

Accessing Multimedia Contents

Multimedia contents are an integral part of the Second Edition of the Springer Handbook of Robotics. 69 chapters contain video icons like this one:

Each icon indicates a video ID that can be used to access individual videos in various simple and intuitive ways.

Using the Multimedia App

We recommend using the multimedia app for smartphone and tablet PCs. You can install the app on *iOS* and *Android* devices using the QR code below. The app allows you to simply scan the pages of the book and automatically play all videos on your device while reading the book.

Multimedia Contents

Using the Website: <http://handbookofrobotics.org>

All chapter videos and part videos can be accessed directly from the website of the multimedia extension. Just enter a video ID in the search field in the top right corner of the website. You may also use the website to browse through chapter and part videos.

Using PDF Files

If you read an electronic copy of the Handbook, each video icon contains a hyper link. Just click on the link to watch the corresponding video.

Using QR Codes

Each chapter starts with a QR code that contains a link to all videos of the chapter. Part videos can be accessed through the QR code at the beginning of each part.

 Part D Manipulation and Interfaces		
36	Motion for Manipulation Tasks	
	<i>James Kuffner, Jing Xiao</i>	897
36.1	Overview	898
36.2	Task-Level Control	900
36.3	Manipulation Planning	904
36.4	Assembly Motion	911
36.5	Unifying Feedback Control and Planning.....	918
36.6	Conclusions and Further Reading.....	920
	Video-References	923
	References	923
37	Contact Modeling and Manipulation	
	<i>Imin Kao, Kevin M. Lynch, Joel W. Burdick</i>	931
37.1	Overview	931
37.2	Kinematics of Rigid-Body Contact	932
37.3	Forces and Friction	936
37.4	Rigid-Body Mechanics with Friction	939
37.5	Pushing Manipulation	942
37.6	Contact Interfaces and Modeling.....	943
37.7	Friction Limit Surface.....	946
37.8	Contacts in Grasping and Fixture Designs	949
37.9	Conclusions and Further Reading.....	950
	Video-References	951
	References	951
38	Grasping	
	<i>Domenico Prattichizzo, Jeffrey C. Trinkle</i>	955
38.1	Models and Definitions	956
38.2	Controllable Twists and Wrenches	961
38.3	Compliant Grasps	965
38.4	Restraint Analysis	967

38.5	Examples	975
38.6	Conclusion and Further Reading	985
	Video-References	986
	References	986
39	Cooperative Manipulation	
	<i>Fabrizio Caccavale, Masaru Uchiyama</i>	989
39.1	Historical Overview	990
39.2	Kinematics and Statics	991
39.3	Cooperative Task Space	995
39.4	Dynamics and Load Distribution	996
39.5	Task-Space Analysis	998
39.6	Control	999
39.7	Conclusions and Further Reading	1003
	Video-References	1004
	References	1004
40	Mobility and Manipulation	
	<i>Oliver Brock, Jaeheung Park, Marc Toussaint</i>	1007
40.1	Grasping and Manipulation	1009
40.2	Control	1013
40.3	Motion Generation	1017
40.4	Learning	1021
40.5	Perception	1025
40.6	Conclusions and Further Reading	1029
	Video-References	1029
	References	1030
41	Active Manipulation for Perception	
	<i>Anna Petrovskaya, Kaijen Hsiao</i>	1037
41.1	Perception via Manipulation	1037
41.2	Object Localization	1038
41.3	Learning About an Object	1049
41.4	Recognition	1054
41.5	Conclusions	1057
	Video-References	1058
	References	1058
42	Haptics	
	<i>Blake Hannaford, Allison M. Okamura</i>	1063
42.1	Overview	1064
42.2	Haptic Device Design	1068
42.3	Haptic Rendering	1071
42.4	Control and Stability of Force Feedback Interfaces	1073
42.5	Other Types of Haptic Interfaces	1075
42.6	Conclusions and Further Reading	1079
	References	1079
43	Telerobotics	
	<i>Günter Niemeyer, Carsten Preusche, Stefano Stramigioli, Dongjun Lee</i>	1085
43.1	Overview and Terminology	1085

43.2	Telerobotic Systems and Applications	1087
43.3	Control Architectures	1090
43.4	Bilateral Control and Force Feedback	1095
43.5	Emerging Applications of Telerobotics	1101
43.6	Conclusions and Further Reading	1104
	Video-References	1104
	References	1105
44	Networked Robots	
	<i>Dezhen Song, Ken Goldberg, Nak-Young Chong</i>	1109
44.1	Overview and Background	1109
44.2	A Brief History	1110
44.3	Communications and Networking	1112
44.4	Properties of Networked Robots	1115
44.5	Cloud Robotics	1121
44.6	Conclusion and Future Directions	1125
	Video-References	1126
	References	1126
 Part E Moving in the Environment		
45	World Modeling	
	<i>Wolfram Burgard, Martial Hebert, Maren Bennewitz</i>	1135
45.1	Historical Overview	1136
45.2	Models for Indoors and Structured Environments	1137
45.3	World and Terrain Models for Natural Environments	1141
45.4	Dynamic Environments	1149
45.5	Summary and Further Reading	1149
	Video-References	1150
	References	1150
46	Simultaneous Localization and Mapping	
	<i>Cyrril Stachniss, John J. Leonard, Sebastian Thrun</i>	1153
46.1	SLAM: Problem Definition	1154
46.2	The Three Main SLAM Paradigms	1157
46.3	Visual and RGB-D SLAM	1166
46.4	Conclusion and Future Challenges	1169
	Video-References	1170
	References	1171
47	Motion Planning and Obstacle Avoidance	
	<i>Javier Minguez, Florant Lamiraux, Jean-Paul Laumond</i>	1177
47.1	Nonholonomic Mobile Robots: Where Motion Planning Meets Control Theory	1178
47.2	Kinematic Constraints and Controllability	1179
47.3	Motion Planning and Small-Time Controllability	1180
47.4	Local Steering Methods and Small-Time Controllability	1181
47.5	Robots and Trailers	1184
47.6	Approximate Methods	1186
47.7	From Motion Planning to Obstacle Avoidance	1187

47.8	Definition of Obstacle Avoidance	1187
47.9	Obstacle Avoidance Techniques	1188
47.10	Robot Shape, Kinematics, and Dynamics in Obstacle Avoidance	1194
47.11	Integration Planning – Reaction	1196
47.12	Conclusions, Future Directions, and Further Reading	1198
	Video-References	1199
	References	1199
48	Modeling and Control of Legged Robots	
	<i>Pierre-Brice Wieber, Russ Tedrake, Scott Kuindersma</i>	1203
48.1	A Brief History of Legged Robots	1204
48.2	The Dynamics of Legged Locomotion	1204
48.3	Stability Analysis – Not Falling Down	1209
48.4	Generation of Dynamic Walking and Running Motions	1214
48.5	Motion and Force Control	1222
48.6	Towards More Efficient Walking	1225
48.7	Different Contact Behaviors	1227
48.8	Conclusion	1228
	References	1228
49	Modeling and Control of Wheeled Mobile Robots	
	<i>Claude Samson, Pascal Morin, Roland Lenain</i>	1235
49.1	Background	1236
49.2	Control Models	1238
49.3	Adaptation of Control Methods for Holonomic Systems	1240
49.4	Methods Specific to Nonholonomic Systems	1241
49.5	Path Following in the Case of Nonideal Wheel-Ground Contact	1255
49.6	Complementary Issues and Bibliographical Guide	1261
	Video-References	1263
	References	1263
50	Modeling and Control of Robots on Rough Terrain	
	<i>Keiji Nagatani, Genya Ishigami, Yoshito Okada</i>	1267
50.1	Overview	1268
50.2	Modeling of Wheeled Robot in Rough Terrain	1270
50.3	Control of Wheeled Robot in Rough Terrain	1274
50.4	Modeling of Tracked Vehicle on Rough Terrain	1276
50.5	Stability Analysis of Tracked Vehicles	1278
50.6	Control of Tracked Vehicle on Rough Terrain	1279
50.7	Summary	1281
	Video-References	1281
	References	1282
51	Modeling and Control of Underwater Robots	
	<i>Gianluca Antonelli, Thor I. Fossen, Dana R. Yoerger</i>	1285
51.1	The Expanding Role of Marine Robotics in Oceanic Engineering	1285
51.2	Underwater Robotics	1287
51.3	Applications	1302
51.4	Conclusions and Further Reading	1303
	Video-References	1304
	References	1304

52 Modeling and Control of Aerial Robots	
<i>Robert Mahony, Randal W. Beard, Vijay Kumar</i>	1307
52.1 Overview	1307
52.2 Modeling Aerial Robotic Vehicles	1309
52.3 Control	1316
52.4 Trajectory Planning	1324
52.5 Estimating the Vehicle State	1328
52.6 Conclusion	1330
Video-References	1331
References	1331

53 Multiple Mobile Robot Systems	
<i>Lynne E. Parker, Daniela Rus, Gaurav S. Sukhatme</i>	1335
53.1 History	1336
53.2 Architectures for Multirobot Systems	1337
53.3 Communication	1339
53.4 Networked Mobile Robots	1340
53.5 Swarm Robots	1351
53.6 Modular Robotics	1354
53.7 Heterogeneity	1357
53.8 Task Allocation	1359
53.9 Learning	1361
53.10 Applications	1362
53.11 Conclusions and Further Reading	1366
Video-References	1366
References	1367

Part F Robots at Work

54 Industrial Robotics	
<i>Martin Hägele, Klas Nilsson, J. Norberto Pires, Rainer Bischoff</i>	1385
54.1 Industrial Robotics: The Main Driver for Robotics Research and Application	1386
54.2 A Short History of Industrial Robots	1386
54.3 Industrial Robot Kinematics	1392
54.4 Typical Industrial Robot Applications	1393
54.5 Safe Human–Robot Collaboration	1405
54.6 Task Descriptions – Teaching and Programming	1409
54.7 System Integration	1414
54.8 Outlook and Long-Term Challenges	1416
Video-References	1418
References	1418

55 Space Robotics	
<i>Kazuya Yoshida, Brian Wilcox, Gerd Hirzinger, Roberto Lampariello</i>	1423
55.1 Historical Developments and Advances of Orbital Robotic Systems	1424
55.2 Historical Developments and Advances of Surface Robotic Systems	1430
55.3 Mathematical Modeling	1437
55.4 Future Directions of Orbital and Surface Robotic Systems	1452
55.5 Conclusions and Further Reading	1457

Video-References	1457
References	1458
56 Robotics in Agriculture and Forestry	
<i>Marcel Bergerman, John Billingsley, John Reid, Eldert van Henten</i>	1463
56.1 Section Scope	1464
56.2 Challenges and Opportunities	1465
56.3 Case Studies	1467
56.4 Conclusion	1487
Video-References	1488
References	1489
57 Robotics in Construction	
<i>Kamel S. Saidi, Thomas Bock, Christos Georgoulas</i>	1493
57.1 Overview	1494
57.2 Offsite Applications of Robotics in Construction	1499
57.3 Onsite Applications of Single Task Construction Robots	1504
57.4 Integrated Robotized Construction Sites	1511
57.5 Currently Unsolved Technical Problems	1514
57.6 Future Directions	1516
57.7 Conclusions and Further Reading	1516
Video-References	1517
References	1517
58 Robotics in Hazardous Applications	
<i>James Trevelyan, William R. Hamel, Sung-Chul Kang</i>	1521
58.1 Operation in Hazardous Environments: The Need for a Robotics Solution	1521
58.2 Applications	1523
58.3 Enabling Technologies	1537
58.4 Conclusions and Further Reading	1544
Video-References	1545
References	1546
59 Robotics in Mining	
<i>Joshua A. Marshall, Adrian Bonchis, Eduardo Nebot, Steven Scheduling</i>	1549
59.1 Modern Mining Practice	1550
59.2 Surface Mining	1552
59.3 Underground Mining	1562
59.4 Challenges and Industry Acceptance	1568
59.5 Challenges, Outlook, and Conclusion	1569
Video-References	1571
References	1572
60 Disaster Robotics	
<i>Robin R. Murphy, Satoshi Tadokoro, Alexander Kleiner</i>	1577
60.1 Overview	1578
60.2 Disaster Characteristics and Impact on Robots	1581
60.3 Robots Actually Used at Disasters	1582
60.4 Robots at the Fukushima-Daiichi Nuclear Power Plant Accident	1588
60.5 Lessons Learned, Challenges, and Novel Approaches	1591

60.6	Evaluation	1598
60.7	Conclusions and Further Reading	1600
	Video-References	1601
	References	1601
61	Robot Surveillance and Security	
	<i>Wendell H. Chun, Nikolaos Papanikolopoulos</i>	1605
61.1	Overview	1605
61.2	Application Domains	1607
61.3	Enabling Technologies	1608
61.4	Active Research	1617
61.5	Conclusion	1622
	Video-References	1623
	References	1623
62	Intelligent Vehicles	
	<i>Alberto Broggi, Alex Zelinsky, Ümit Özgüner, Christian Laugier</i>	1627
62.1	The Motivation and Approaches to Intelligent Vehicles	1628
62.2	Enabling Technologies	1632
62.3	Road Scene Understanding	1635
62.4	Advanced Driver Assistance	1639
62.5	Driver Monitoring	1645
62.6	Towards Fully Autonomous Vehicles	1647
62.7	Future Trends and Prospects	1650
62.8	Conclusions and Further Reading	1651

Part G Robots and Humans

67 Humanoids	
<i>Paul Fitzpatrick, Kensuke Harada, Charles C. Kemp, Yoshio Matsumoto, Kazuhito Yokoi, Eiichi Yoshida</i>	1789
67.1 Why Humanoids?	1789
67.2 History	1792
67.3 What to Immitate?	1794
67.4 Locomotion	1795
67.5 Whole-Body Activities	1801
67.6 Morphological Communication	1809
67.7 Conclusions and Further Reading	1813
Video-References	1813
References	1813
68 Human Motion Reconstruction	
<i>Katsu Yamane, Wataru Takano</i>	1819
68.1 Overview	1819
68.2 Models and Computations	1820
68.3 Reconstruction for Understanding	1825
68.4 Reconstruction for Robots	1829
Video-References	1830
References	1831
69 Physical Human-Robot Interaction	
<i>Sami Haddadin, Elizabeth Croft</i>	1835
69.1 Classification	1836
69.2 Human Safety	1839
69.3 Human-Friendly Robot Design	1847
69.4 Control for Physical Interaction	1853
69.5 Motion Planning for Human Environments	1859
69.6 Interaction Planning	1862

69.7	Conclusions and Challenges	1867
	Video-References	1868
	References	1869
70	Human-Robot Augmentation	
	<i>Massimo Bergamasco, Hugh Herr</i>	1875
70.1	Concept and Definitions	1876
70.2	Upper Limb Wearable Systems	1877
70.3	Lower Limb Wearable Systems	1882
70.4	Whole Body Wearable Systems	1889
70.5	Control of Human-Robot Augmentation Systems	1892
70.6	Conclusions and Further Developments	1902
	Video-References	1902
	References	1902
71	Cognitive Human-Robot Interaction	
	<i>Bilge Mutlu, Nicholas Roy, Selma Šabanović</i>	1907
71.1	Human Models of Interaction	1908
71.2	Robot Models of Interaction	1914
71.3	Models of Human-Robot Interaction	1916
71.4	Conclusion and Further Reading	1927
	Video-References	1927
	References	1928
72	Social Robotics	
	<i>Cynthia Breazeal, Kerstin Dautenhahn, Takayuki Kanda</i>	1935
72.1	Overview	1936
72.2	Social Robot Embodiment	1936
72.3	Social Robots and Social-Emotional Intelligence	1938
72.4	Socio-Cognitive Skills	1941
72.5	Human Social Responses to Social Robots	1944
72.6	Social Robots and Communication Skills	1946
72.7	Long-Term Interaction with Robot Companions	1950
72.8	Tactile Interaction with Social Robots	1954
72.9	Social Robots and Teamwork	1958
72.10	Conclusion	1959
72.11	Further Reading	1960
	Video-References	1960
	References	1961
73	Socially Assistive Robotics	
	<i>Maja J. Matarić, Brian Scassellati</i>	1973
73.1	Overview	1973
73.2	The Need for Socially Assistive Robotics	1974
73.3	Advantages of Embodied Robots over Virtual Agents	1975
73.4	Motivation, Autonomy, and Companionship	1977
73.5	Influence and the Dynamics of Assistive Interaction	1978
73.6	Personalization and Adaptation to Specific Needs and Abilities	1978
73.7	Creating Long-Term Engagement and Behaviour Change	1979
73.8	SAR for Autism Spectrum Disorder (ASD) Therapy	1980
73.9	SAR Supporting Rehabilitation	1982

73.10	SAR and Eldercare	1985
73.11	SAR for Alzheimer's Dementia and Cognitive Rehabilitation	1986
73.12	Ethical and Safety Considerations.....	1987
	References	1988

Abbreviations

Symbols

k -NN	k -nearest neighbor
0-D	zero-dimensional
1-D	one-dimensional
2-D	two-dimensional
2.5-D	two-and-a-half-dimensional
3-D	three-dimensional
3-D-NDT	three-dimensional!normal distributions transform
4-D	four-dimensional
6-D	six-dimensional
6R	six-revolute
7R	seven-revolute

A

A&F	agriculture and forestry
AA	agonist–antagonist
AAAI	American Association for Artificial Intelligence
AAAI	Association for the Advancement of Artificial Intelligence
AAL	ambient assisted living
ABA	articulated-body algorithm
ABF	artificial bacterial flagella
ABRT	automated!bus rapid transit
ABS	acrylonitrile–butadiene–styrene
AC	aerodynamic center
AC	alternating current
ACARP	Australian Coal Association Research Program
ACBS	automatic!constructions building system
ACC	adaptive cruise control
ACFV	autonomous!combat flying vehicle
ACM	active chord mechanism
ACM	active cord mechanism
ACT	anatomically correct testbed
ADAS	advanced driving assistance system
ADC	analog digital converter
ADCP	acoustic Doppler current profiler
ADL	activities for daily living
ADSL	asymmetric digital subscriber line
AFC	alkaline fuel cell
AFC	armoured (or articulated) face conveyor
AFM	atomic force microscope
AFV	autonomous!flying vehicle
AGV	autonomous guided vehicle
AGV	automated!guided vehicle

AHRS	attitude and heading reference system
AHS	advanced highway system
AI	artificial intelligence
AIAA	American Institute of Aeronautics and Astronautics
AIM	assembly incidence matrix
AIP	air-independent power
AIP	anterior intraparietal sulcus
AIP	anterior interparietal area
AIS	artificial intelligence system
AIST	Institute of Advanced Industrial Science and Technology
AIST	Japan National Institute of Advanced Industrial Science and Technology
AIST	National Institute of Advanced Industrial Science and Technology (Japan)
AIT	anterior inferotemporal cortex
ALEX	active leg exoskeleton
AM	actuator for manipulation
AMASC	actuator with mechanically adjustable series compliance
AMC	Association for Computing Machinery
AMD	autonomous!mental development
AMM	audio-motor map
ANN	artificial neural network
AO	Arbeitsgemeinschaft für Osteosynthesefragen
AOA	angle of attack
AP	antipersonnel
APF	annealed particle filter
APG	adjustable pattern generator
API	application programming interface
APOC	allowing dynamic selection and changes
AR	autoregressive
aRDnet	agile robot development network
ARM	Acorn RISC machine architecture
ARM	assistive!robot service manipulator
ARX	auto regressive estimator
ASAP	adaptive sampling and prediction
ASCII	American standard code for information interchange
ASD	autism spectrum disorder
ASIC	application-specific integrated circuit
ASIC	application-specific feature transform
ASIMO	advanced step in innovative mobility
ASK	amplitude shift keying
ASL	autonomous systems laboratory
ASM	advanced servomanipulator

ASN	active sensor network
ASR	automatic!spoken-language recognition
ASR	automatic!speech recognition
ASTRO	autonomous!space transport robotic operations
ASV	adaptive suspension vehicle
ASyMTRe	automated!synthesis of multirobot task solutions through software reconfiguration
AT	anti-tank mine
ATHLETE	all-terrain hex-legged extra-terrestrial explorer
ATLANTIS	a three layer architecture for navigating through intricate situations
ATLSS	advanced technology for large structural systems
ATR	automatic!target recognition
AuRA	autonomous robot architecture
AUV	autonomous underwater vehicle
AUV	autonomous aquatic vehicle
AUVAC	Autonomous Undersea Vehicles Application Center
AUVSI	Association for Unmanned Vehicle Systems International
AV	anti-vehicle

B

B/S	browser/server
B2B	business to business
BCI	brain-computer interface
BE	body extender
BEMT	blade element momentum theory
BEST	boosting!engineering science and technology
BET	blade element theory
BFA	bending fluidic actuator
BFP	best-first-planner
BI	brain imaging
BIP	behavior-interaction-priority
BLE	broadcast of local eligibility
BLEEX	Berkely exoskeleton
BLUE	best linear unbiased estimator
BML	behavior!mark-up language
BMS	battery management system
BN	Bayesian network
BOM	bill of material
BOw	bag-of-word
BP	behavior primitive
BP	base plate
BRICS	best practice in robotics
BRT	bus rapid transit
BWSTT	body-weight supported treadmill training

C

C	cylindrical joint
C/A	coarse-acquisition
C/S	client/server
CA	collision avoidance
CACC	cooperative adaptive cruise control
CAD	computer-aided drafting
CAD	computer-aided design
CAE	computer-aided engineering
CALM	communication access for land mobiles
CAM	computer-aided manufacturing
CAN	controller area network
CARD	computer-aided remote driving
CARE	coordination action for robotics in Europe
CASA	Civil Aviation Safety Authority
CASALA	Centre for Affective Solutions for Ambient Living Awareness
CASPER	continuous activity scheduling, planning, execution and replanning
CAT	collision avoidance technology
CAT	computer-aided tomography
CB	computational brain
CB	cluster bomb
CBRNE	chemical, biological, nuclear, radiological, or explosive
CC	compression criterion
CCD	charge-coupled device
CCD	charge-coupled detector
CCI	control command interpreter
CCP	coverage configuration protocol
CCT	conservative congruence transformation
CCW	counterclockwise
CC&D	camouflage, concealment, and deception
CD	collision detection
CD	committee draft
CD	compact disc
CDC	cardinal direction calculus
CDOM	colored dissolved organic matter
CE	computer ethic
CEA	Commissariat à l'Énergie Atomique
CEA	Atomic Energy Commission
CEBOT	cellular robotic system
CEC	Congress on Evolutionary Computation
CEPE	Computer Ethics Philosophical Enquiry
CES	Consumer Electronics Show
CF	carbon fiber
CF	contact formation
CF	climbing fiber
CFD	computational fluid dynamics
CFRP	carbon fiber reinforced prepreg
CFRP	carbon fiber reinforced plastic
CG	center of gravity

CG	computer graphics	CP	continuous path
CGI	common gateway interface	CP	cerebral palsy
CHMM	coupled!hidden Markov model	CPG	central pattern generation
CHMM	continuous hidden Markov model	CPG	central pattern generator
CIC	computer integrated construction	CPS	cyber physical system
CIE	International Commission on Illumination	CPSR	Computer Professional for Social Responsibility
CIP	Children's Innovation Project	CPU	central processing unit
CIRCA	cooperative intelligent real-time control architecture	CRASAR	Center for Robot-Assisted Search and Rescue
CIS	computer-integrated surgery	CRBA	composite-rigid-body algorithm
CLARAty	coupled layered architecture for robot autonomy	CRF	conditional random field
CLEaR	closed-loop execution and recovery	CRLB	Cramér–Rao lower bound
CLIK	closed-loop inverse kinematics	CSAIL	Computer Science and Artificial Intelligence Laboratory
CMAC	cerebellar model articulation controller	CSIRO	Commonwealth Scientific and Industrial Research Organisation
CMCs	ceramic matrix composite	CSMA	carrier-sense multiple-access
CML	concurrent!mapping and localization	CSP	constraint satisfaction problem
CMM	coordinate measurement machine	CSSF	Canadian Scientific Submersible Facility
CMOMMT	cooperative multirobot observation of multiple moving target	CT	computed tomography
CMOS	complementary metal-oxide-semiconductor	CTFM	continuous-transmission frequency modulation
CMP	centroid moment pivot	CU	control unit
CMTE	Cooperative Research Centre for Mining Technology and Equipment	cv-SLAM	ceiling vision SLAM
CMU	Carnegie Mellon University	CVD	chemical vapor deposition
CNC	computer numerical control	CVIS	cooperative vehicle infrastructure system
CNN	convolutional neural network	CVT	continuous variable transmission
CNP	contract net protocol	CW	clockwise
CNRS	Centre National de la Recherche Scientifique	CWS	contact!wrench sum
CNT	carbon nanotube		
COCO	common objects in context		
COG	center of gravity	D	distal
COM	center of mass	D/A	digital-to-analog
COMAN	compliant humanoid platform	DAC	digital analog converter
COMEST	Commission mondiale d'éthique des connaissances scientifiques et des technologies	DARPA	Defense Advanced Research Projects Agency
COMINT	communication intelligence	DARS	distributed!autonomous robotic systems
CONE	Collaborative Observatory for Nature Environments	DBN	dynamic Bayesian network
COP	center of pressure	DBN	deep belief network
CoP	center of pressure	DC	disconnected
COR	center of rotation	DC	direct current
CORBA	common object request broker architecture	DC	dynamic!constrained
CORS	continuous operating reference station	DCS	dynamic covariance scaling
COT	cost!of transport	DCT	discrete!cosine transform
COTS	commercial off-the-shelf	DD	differentially driven
COV	characteristic output vector	DDD	dangerous, dirty, and dreary
CP	complementarity problem	DDF	decentralized data fusion
CP	capture point	DDP	differential dynamic programming
		DDS	data distribution service
		DEA	differential elastic actuator
		DEM	discrete!element method

DFA	design!for assembly	EDM	electrical discharge machining
DFRA	distributed field robot architecture	EE	end-effector
DFT	discrete Fourier transform	EEG	electroencephalography
DGPS	differential global positioning system	EGNOS	European Geostationary Navigation Overlay Service
DH	Denavit–Hartenberg	EHC	enhanced horizon control
DHMM	discrete!hidden Markov model	EHPA	exoskeleton!for human performance augmentation
DHS	US Department of Homeland Security	EKF	extended Kalman filter
DIRA	distributed!robot architecture	ELS	ethical, legal and societal
DIST	Dipartimento di Informatica Sistemica e Telematica	EM	expectation maximization
DL	description logic	emf	electromotive force
DLR	Deutsches Zentrum für Luft- und Raumfahrt	EMG	electromyography
DLR	German Aerospace Center	EMIB	emotion, motivation and intentional behavior
DMFC	direct methanol fuel cell	EMS	electrical!master–slave manipulator
DMP	dynamic movement primitive	EO	electrooptical
DNA	deoxyribonucleic acid	EO	elementary operator
DNF	dynamic!neural field	EOA	end of arm
DOD	Department of Defense	EOD	explosive!ordnance disposal
DOF	degree of freedom	EP	exploratory procedure
DOG	difference of Gaussian	EP	energy packet
DOP	dilution of precision	EPFL	Ecole Polytechnique Fédérale de Lausanne
DPLL	Davis–Putnam algorithm	EPP	extended!physiological proprioception
DPM	deformable part model	EPS	expandable polystyrene
DPN	dip-pen nanolithography	ER	electrorheological
DPSK	differential phase shift keying	ER	evolutionary!robotics
DRIE	deep reactive ion etching	ERA	European robotic arm
DSM	dynamic!state machine	ERP	enterprise resource planning
DSO	Defense Sciences Office	ERSP	evolution robotics software platform
DSP	digital signal processor	ES	electrical!stimulation
DSRC	dedicated short-range communications	ESA	European Space Agency
DU	dynamic!unconstrained	ESC	electronic speed controller
DVL	Doppler velocity log	ESL	execution support language
DWA	dynamic window approach	ESM	energy!stability margin
DWDM	dense wave division multiplex	ESM	electric support measure
D&D	deactivation and decommissioning	ETL	Electro-Technical Laboratory
E		ETS-VII	Engineering Test Satellite VII
e-beam	electron-beam	EU	European Union
EAP	electroactive polymer	EURON	European Robotics Research Network
EBA	energy bounding algorithm	EVA	extravehicular activity
EBA	extrastriate body part area	EVERYON	evolving morphologies for human–robot symbiotic interaction
EBID	electron-beam induced deposition		
EC	externally connected		
EC	exteroception		
ECAI	European Conference on Artificial Intelligence	F	
ECD	eddy current damper	F5	frontal area 5
ECEF	earth-centred, earth-fixed	FAA	Federal Aviation Administration
ECER	European Conference on Educational Robotics	FAO	Food and Agriculture Organization
ECG	electrocardiogram	FARS	Fagg–Arbib–Rizzolatti–Sakata
ECU	electronics controller unit	FARSA	framework for autonomous robotics simulation and analysis

fastSLAM	fast simultaneous localization and mapping
FB-EHPA	full-body EHPA
FCU	flight control-unit
FD	friction damper
FDA	US Food and Drug Association
FDM	fused deposition modeling
FE	finite element
FEA	finite element analysis
FEM	finite element method
FESEM	field-emission SEM
FF	fast forward
FFI	Norwegian defense research establishment
FFT	fast Fourier transform
FIFO	first-in first-out
FIRA	Federation of International Robot-soccer Association
FIRRE	family of integrated rapid response equipment
FIRST	For Inspiration and Recognition of Science and Technology
FI-UAS	flapping wing unmanned aerial system
FLIR	forward!looking infrared
FMBT	feasible minimum buffering time
FMCW	frequency modulation continuous wave
fMRI	functional!magnetic resonance imaging
FMS	flexible!manufacturing system
FNS	functional!neural stimulation
FOA	focus of attention
FOG	fiber-optic gyro
FOPEN	foliage penetration
FOPL	first-order predicate logic
FOV	field of view
FP	fusion primitive
FPGA	field-programmable gate array
FR	false range
FRI	foot rotation indicator
FRP	fiber-reinforced plastics
FRP	fiber-reinforced prepreg
fs	force!sensor
FSA	finite-state acceptor
FSK	frequency shift keying
FSR	force sensing resistor
FSW	friction!stir welding
FTTH	fiber to the home
FW	fixed-wing

G

GA	genetic algorithm
GAPP	goal as parallel programs
GARNICS	gardening with a cognitive system
GAS	global asymptotic stability

GBAS	ground based augmentation system
GCDC	Grand Cooperative Driving Challenge
GCER	Global Conference on Educational Robotics
GCR	goal-contact relaxation
GCS	ground!control station
GDP	gross!domestic product
GenoM	generator of modules
GEO	geostationary Earth orbit
GF	grapple fixture
GFRP	glass-fiber reinforced plastic
GI	gastrointestinal
GIB	GPS intelligent buoys
GICHD	Geneva International Centre for Humanitarian Demining
GID	geometric!intersection data
GIE	generalized-inertia ellipsoid
GIS	geographic information system
GJM	generalized!Jacobian matrix
GLONASS	globalnaya navigatsionnaya sputnikovaya sistema
GLS	global navigation satellite system
GMAW	gas-shielded metal arc welding
GMM	Gaussian mixture model
GMSK	Gaussian minimum shift keying
GMTI	ground!moving target indicator
GNC	guidance, navigation, and control
GO	golgi!tendon organ
GP	Gaussian process
GPCA	generalized principal component analysis
GPRS	general!packet radio service
GPS	global positioning system
GPU	graphics processing unit
GRAB	guaranteed recursive adaptive bounding
GRACE	graduate robot attending conference
GraWoLF	gradient-based win or learn fast
GSD	geon structural description
GSN	gait sensitivity norm
GSP	Gough–Stewart platform
GUI	graphical user interface
GV	ground vehicle
GVA	gross!value added
GZMP	generalized!ZMP

H

H	helical joint
HAL	hybrid!assistive limb
HAMMER	hierarchical!attentive multiple models for execution and recognition
HASY	hand!arm system
HBBA	hybrid behavior-based architecture
HCI	human–computer interaction

HD	high definition	IARC	International Aerial Robotics Competition
HD	haptic device	IAS	intelligent!autonomous system
HD-SDI	high-definition serial digital interface	IBVS	image-based visual servo control
HDSSL	high data rate digital subscriber line	IC	integrated chip
HE	hand!exoskeleton	IC	integrated circuit
HF	hard finger	ICA	independent!component analysis
HF	histogram filter	ICAPS	International Conference on Automated Planning and Scheduling
HFAC	high frequency alternating current	ICAR	International Conference on Advanced Robotics
HHMM	hierarchical!hidden Markov model	ICBL	International Campaign to Ban Landmines
HIC	head injury criterion	ICC	instantaneous center of curvature
HI	Hybrid III dummy	ICE	internet communications engine
HIP	haptic interaction point	ICP	iterative closest point
HJB	Hamilton–Jacobi–Bellman	ICR	instantaneous center of rotation
HJI	Hamilton–Jacobi–Isaac	ICRA	International Conference on Robotics and Automation
HMCS	human–machine!cooperative system	ICT	information!and communication technology
HMD	head-mounted display	ID	inside diameter
HMDS	hexamethyldisilazane	ID	identifier
HMI	human–machine!interaction	IDE	integrated!development environment
HMI	human–machine!interface	IDL	interface definition language
HMM	hidden Markov model	IE	information!ethics
HO	human operator	IED	improvised explosive device
HOG	histogram of oriented gradient	IEEE	Institute of Electrical and Electronics Engineers
HOG	histogram of oriented features	IEKF	iterated extended Kalman filter
HPC	high-performance computing	IETF	internet!engineering task force
HRI	human–robot interaction	IFA	Internationale Funk Ausstellung
HRI/OS	HRI operating system	IFOG	interferometric fiber-optic gyro
HRP	humanoid robotics project	IFR	International Federation of Robotics
HRR	high resolution radar	IFREMER	Institut français de recherche pour l’exploitation de la mer
HRTEM	high-resolution transmission electron microscope	IFRR	International Foundation of Robotics Research
HSGR	high safety goal	IFSAR	interferometric SAR
HST	Hubble space telescope	IHIP	intermediate haptic interaction point
HSTAMIDS	handheld standoff mine detection system	IIR	infinite impulse response
HSWR	high safety wide region	IIS	Internet Information Services
HTAS	high tech automotive system	IIT	Istituto Italiano di Tecnologia
HTML	hypertext markup language	IJCAI	International Joint Conference on Artificial Intelligence
HTN	hierarchical task network	IK	inverse kinematics
HTTP	hypertext transmission protocol	ILLS	instrumented logical sensor system
HW/SW	hardware/software	ILO	International Labor Organization
<hr/>		ILQR	iterative linear quadratic regulator
I/O	input/output	IM	injury measure
I3CON	industrialized, integrated, intelligent, construction	IMAV	International Micro Air Vehicles
IA	interval algebra	IMTS	intelligent!multimode transit system
IA	instantaneous!allocation	IMU	inertial measurement unit
IAA	interaction!agent	INS	inertia navigation system
IAB	International Association of Bioethics		
IACAP	International Association for Computing and Philosophy		
IAD	interaural amplitude difference		
IAD	intelligent!assisting device		

INS	inertial navigation system	JAEA	Japan Atomic Energy Agency
IO	input output	JAMSTEC	Japan Agency for Marine-Earth Science and Technology
IO	inferior olive		
IOSS	input-output-to-state stability	JAMSTEC	Japan Marine Science and Technology Center
IP	internet protocol		
IP	interphalangeal	JAUS	joint architecture for unmanned systems
IPA	Institute for Manufacturing Engineering and Automation	JAXA	Japan Aerospace Exploration Agency
		JDL	joint directors of laboratories
IPC	interprocess communication	JEM	Japan Experiment Module
IPC	international AI planning competition	JEMRMS	Japanese experiment module remote manipulator system
IPMC	ionic polymer-metal composite		
IPR	intellectual property right	JHU	Johns Hopkins University
IR	infrared	JND	just noticeable difference
IRB	Institutional Review Board	JPL	Jet Propulsion Laboratory
IREDES	International Rock Excavation Data Exchange Standard	JPS	jigsaw positioning system
		JSC	Johnson Space Center
IRL	in real life	JSIM	joint-space inertia matrix
IRL	inverse!reinforcement learning	JSP	Java server pages
IRLS	iteratively reweighted least square		
IRNSS	Indian regional navigational satellite system	K	
IROS	Intelligent Robots and Systems	KAIST	Korea Advanced Institute of Science and Technology
IS	importance sampling		
ISA	industrial standard architecture	KERS	kinetic energy recovery system
ISA	international standard atmosphere	KIPR	KISS Institute for Practical Robotics
ISAR	inverse SAR	KLD	Kullback–Leibler divergence
ISDN	integrated services digital network	KNN	k-nearest neighbor
ISE	international submarine engineering	KR	knowledge representation
ISER	International Symposium on Experimental Robotics	KRISO	Korea Research Institute of Ships and Ocean Engineering
ISM	implicit shape model	L	
ISO	International Organization for Standardization		
ISP	Internet service provider	L/D	lift-to-drag
ISR	intelligence, surveillance and reconnaissance	LAAS	Laboratory for Analysis and Architecture of Systems
ISRR	International Symposium of Robotics Research	LADAR	laser radar
		LAGR	learning!applied to ground robots
ISS	international space station	LARC	Lie algebra rank condition
ISS	input-to-state stability	LARS	Laparoscopic Assistant Robotic System
IST	Instituto Superior Técnico	LASC	Longwall Automation Steering Committee
IST	Information Society Technologies		
IT	intrinsic tactile	LBL	long-baseline system
IT	information!technology	LCAUV	long-range cruising AUV
IT	inferotemporal cortex	LCC	life-cycle-costing
ITD	interaural time difference	LCD	liquid-crystal display
IU	interaction!unit	LCM	light-weight communications and marshalling
IV	instrumental variable		
IvP	interval programming	LCP	linear complementarity problem
IWS	intelligent!wheelchair system	LCSP	linear constraint satisfaction program
IxTeT	indexed time table	LDA	latent Dirichlet allocation
		LED	light-emitting diode
J		LENAR	lower!extremity nonanthropomorphic robot

LEO	low!Earth orbit	MDARS	mobile!detection assessment and response system
LEV	leading edge vortex	MDL	minimum description length
LfD	learning!from demonstration	MDP	Markov decision process
LGN	lateral!geniculate nucleus	ME	mechanical!engineering
LHD	load!haul-dump	MEG	magnetoencephalography
LIDAR	light detection and ranging	MEL	Mechanical Engineering Laboratory
LIGA	Lithographie, Galvanoumformung, Abformung	MEMS	microelectromechanical system
LIP	linear inverted pendulum	MEP	motor!evoked potential
LIP	lateral!intraparietal sulcus	MESSIE	multi expert system for scene interpretation and evaluation
LiPo	lithium polymer		
LLC	locality constrained linear coding	MESUR	Mars environmental survey
LMedS	least median of squares	MF	mossy fiber
LMS	laser measurement system	MFI	micromechanical flying insect
LOG	Laplacian of Gaussian	MFSK	multiple FSK
LOPES	lower!extremity powered exoskeleton	MHS	International Symposium on Micro Mechatronics and Human Science
LOS	line-of-sight		
LP	linear program	MHT	multihypothesis tracking
LQG	linear quadratic Gaussian	MIA	mechanical impedance adjuster
LQR	linear quadratic regulator	MIME	mirror!image movement enhancer
LSS	logical sensor system	MIMICS	multimodal immersive motion rehabilitation with interactive cognitive system
LSVM	latent support vector machine		
LtA	lighter-than-air		
LtA-UAS	lighter-than-air system	MIMO	multiple-input–multiple-output
LTL	linear temporal logic	MIP	medial intraparietal sulcus
LVDT	linear variable differential transformer	MIPS	microprocessor without interlocked pipeline stages
LWR	light-weight robot		
M		MIR	mode identification and recovery
		MIRO	middleware for robot
		MIS	minimally invasive surgery
		MIT	Massachusetts Institute of Technology
		MITI	Ministry of International Trade and Industry
MACA	Afghanistan Mine Action Center	MKL	multiple kernel learning
MACCEPA	mechanically adjustable compliance and controllable equilibrium position actuator	ML	machine!learning
MAP	maximum a posteriori	MLE	maximum likelihood estimate
MARS	multiappendage robotic system	MLR	mesencephalic locomotor region
MARUM	Zentrum für Marine Umweltwissenschaften	MLS	multilevel surface map
MASE	Marine Autonomous Systems Engineering	MMC	metal matrix composite
MASINT	measurement!and signatures intelligence	MMMS	multiple master multiple-slave
MAV	micro aerial vehicles	MMSAE	multiple model switching adaptive estimator
MAZE	Micro robot maze contest	MMSE	minimum mean-square error
MBA	motivated behavioral architecture	MMSS	multiple master single-slave
MBARI	Monterey Bay Aquarium Research Institute	MNS	mirror!neuron system
MBE	molecular-beam epitaxy	MOCVD	metallo-organic chemical vapor deposition
MBS	mobile!base system		
MC	Monte Carlo	MOMR	multiple operator multiple robot
MCFC	molten carbonate fuel cell	MOOS	mission oriented operating suite
MCP	magazining, cleaning, plotting	MOOS	motion-oriented operating system
MCP	metacarpophalangeal	MORO	mobile robot
MCS	mission!control system	MOSR	multiple operator single robot
		MP	moving plate
		MPC	model predictive control

MPF	manifold particle filter	NIDRR	National Institute on Disability and Rehabilitation Research
MPFIM	multiple!paired forward-inverse model	NiMH	nickel metal hydride battery
MPHE	multi-phalanx hand exoskeleton	NIMS	networked!infomechanical systems
MPSK	Mary phase shift keying	NIOSH	United States National Institute for Occupational Safety and Health
MQAM	Mary quadrature amplitude modulation	NIRS	near infrared spectroscopy
MR	magnetorheological	NIST	National Institute of Standards and Technology
MR	multiple reflection	NLIS	national livestock identification scheme
MR	multirobot!task	NLP	nonlinear!programming problem
MRAC	model reference adaptive control	NMEA	National Marine Electronics Association
MRDS	Microsoft robotics developers studio	NMF	nonnegative matrix factorization
MRF	Markov random field	NMMI	natural machine motion initiative
MRHA	multiple!resource host architecture	NMR	nuclear!magnetic resonance
MRI	magnetic resonance imaging	NN	neural network
MRSR	Mars rover sample return	NOAA	National Oceanic and Atmospheric Administration
MRTA	multirobot!task allocation	NOAH	navigation!and obstacle avoidance help
MSAS	multifunctional satellite augmentation system	NOC	National Oceanography Centre
MSER	maximally stable extremal region	NOTES	natural!orifice transluminal surgery
MSHA	US Mine Safety and Health Administration	NPO	nonprofit organization
MSK	minimum shift keying	NPS	Naval Postgraduate School
MSL	middle-size league	NQE	national qualifying event
MSM	master-slave!manipulator	NRI	national robotics initiative
MST	microsystem technology	NRM	nanorobotic manipulator
MT	momentum theory	NRTK	network real-time kinematic
MT	multitask	NTTP	nontangential proper part
MT	medial temporal area	NTSC	National Television System Committee
MTBF	mean time between failures	NURBS	nonuniform rational B-spline
MTI	moving target indicator	NUWC	Naval Undersea Warfare Center Division Newport
MVERT	move value estimation for robot teams	NZDF	New Zealand Defence Force
MWNT	multiwalled carbon nanotube		

N

N&G	nursery and greenhouse
NAP	nonaccidental property
NASA	National Aeronautics and Space Agency
NASDA	National Space Development Agency of Japan
NASREM	NASA/NBS standard reference model
NBS	National Bureau of Standards
NC	numerical control
ND	nearness diagram navigation
NDDS	network data distribution service
NDGPS	nationwide different GPS system
NDI	nonlinear dynamic inversion
NDT	normal distributions transform
NEMO	network!mobility
NEMS	nanoelectromechanical system
NEO	neodymium
NERVE	New England Robotics Validation and Experimentation
NESM	normalized ESM

O

OAA	open!agent architecture
OASIS	onboard autonomous science investigation system
OAT	optimal arbitrary time-delay
OBU	on board unit
OC	optimal control
OCPP	optimal!coverage path planning
OCR	OC robotics
OCT	optical!coherence tomography
OCU	operator control unit
OD	outer diameter
ODE	ordinary differential equation
ODE	open dynamics engine
ODI	ordinary differential inclusion
OECD	Organization for Economic Cooperation and Development
OKR	optokinetic response
OLP	offline programming

OM	optical microscope
OM	occupancy map
ONR	US Office of Naval Research
OOF	out of field
OOTL	human!out of the loop control
OPRoS	open platform for robotic service
ORCA	open robot control architecture
ORCCAD	open robot controller computer aided design
ORI	open!roboethics initiative
ORM	obstacle restriction method
OROCOS	open robot control software
ORU	orbital replacement unit
OS	operating system
OSC	operational-space control
OSIM	operational-space inertia matrix
OSU	Ohio State University
OTH	over-the-horizon
OUR-K	ontology based unified robot knowledge
OWL	web ontology language
OxIM	Oxford intelligent machine

P

P	prismatic joint
P&O	prosthetics!and orthotic
PA	point algebra
PACT	perception!for action control theory
PAD	pleasure arousal dominance
PAFC	phosphoric acid fuel cell
PAM	pneumatic artificial muscle
PaMini	pattern-based mixed-initiative
PANi	polyaniline
PANTOMECH	pantograph mechanism driven
PAPA	privacy, accuracy, intellectual property, and access
PAS	pseudo-amplitude scan
PAT	proximity!awareness technology
PB	parametric!bias
PbD	programming!by demonstration
PBVS	pose-based visual servo control
PC	polycarbonate
PC	personal computer
PC	principal contact
PC	passivity controller
PC	proprioception
PC	Purkinje cell
PCA	principal component analysis
PCI	peripheral component interconnect
PCle	peripheral component interconnect express
PCL	point cloud library
PCM	programmable!construction machine
PD	proportional–derivative

PDE	partial differential equation
PDGF	power!data grapple fixture
PDMS	polydimethylsiloxane
PDOP	positional dilution of precision
PDT	proximity!detection technology
PEAS	probing environment and adaptive sleeping protocol
PEFC	polymer electrolyte fuel cell
PEMFC	proton exchange membrane fuel cell
PerceptOR	perception!for off-road robotics
PET	positron emission tomography
PF	particle filter
PF	parallel!fiber
PFC	prefrontal cortex
PFH	point feature histogram
PFM	potential field method
PGM	probabilistic graphical model
PGRL	policy gradient!reinforcement learning
pHRI	physical!human–robot interaction
PI	policy iteration
PI	possible!injury
PI	propositional integral
PI	proportional–integral
PIC	programmable!intelligent computer
PID	proportional–integral–derivative
PIT	posterior!inferotemporal cortex
PKM	parallel kinematics machine
PKM	parallel kinematic machine
PL	power loading
PLC	programmable!logic controller
PLD	programmable!logic device
PLEXIL	plan execution interchange language
PLSA	probabilistic latent semantic analysis
PLZT	lead lanthanum zirconate titanate
PM	permanent magnet
PMC	polymer matrix composite
PMMA	polymethyl methacrylate
PneuNet	pneumatic network
PnP	perspective-n-point
PNT	Petri net transducer
PO	partially overlapping
PO	passivity observer
POE	local product-of-exponential
POI	point!of interest
POM	polyoxymethylene
POMDP	partially observable Markov decision process
POP	partial-order planning
PPS	precise positioning system
PPy	polypyrrole
PR	positive photoresist
PRM	probabilistic roadmap
PRM	probabilistic roadmap method
PRN	pseudo-random noise

PRoP	personal roving presence
ProVAR	professional vocational assistive robot
PRS	procedural reasoning system
PS	power source
PSD	position sensing device
PSD	position-sensitive-device
PSK	phase shift keying
PSPM	passive set-position modulation
PTAM	parallel tracking and mapping
PTU	pan-tilt unit
PUMA	programmable!universal machine for assembly
PVA	position, velocity, and attitude
PVC	polyvinyl chloride
PVD	physical vapor deposition
PVDF	polyvinylidene fluoride
PWM	pulse-width modulation
PwoF	point-contact-without-friction
PZT	lead zirconate titanate

Q

QAM	quadrature amplitude modulation
QD	quantum dot
QID	qualifier, inspection and demonstration
QOLT	quality!of life technology
QOS	quality of service
QP	quadratic programming
QPSK	quadrature phase shift keying
QRIO	quest for curiosity
QSC	quasistatic!constrained
QT	quasistatic telerobotics
QZSS	quasi-zenith satellite system

R

R	revolute joint
R.U.R.	Rossum's Universal Robots
RA	rectangle algebra
RAC	Robotics and Automation Council
RAIM	receiver autonomous integrity monitor
RALF	robotic arm large and flexible
RALPH	rapidly adapting lane position handler
RAM	random!access memory
RAMS	robot-assisted microsurgery
RAMS	random!access memory system
RANSAC	random sample consensus
RAP	reactive action package
RAS	Robotics and Automation Society
RBC	recognition!by-component
RBF	radial!basis function network
RBF	radial!basis function
RBT	robot!experiment
RC	radio control

RC	robot!controller
RCC	region connection calculus
RCC	remote center of compliance
RCM	remote!center of motion
RCP	rover chassis prototype
RCR	responsible conduct of research
RCS	real-time control system
RCS	rig control system
RDT	rapidly exploring dense tree
RECS	robotic!explosive charging system
REINFORCE	reward increment = nonnegative factor × offset reinforcement × characteristic eligibility
RERC	Rehabilitation Engineering Research Center
RF	radio frequency
RFID	radio frequency identification
RG	rate gyro
RGB-D	color camera with depth
RGB-D	red green blue distance
RGB-D	red-green-blue-depth
RHIB	rigid!hull inflatable boat
RIE	reactive-ion etching
RIG	rate-integrating gyro
RISC	reduced instruction set computer
RL	reinforcement learning
RLG	ring laser gyroscope
RLG	random loop generator
RMC	resolved momentum control
RMDP	relational Markov decision processes
RMMS	reconfigurable modular manipulator system
RMS	root mean square
RNDF	route network definition file
RNEA	recursive Newton-Euler algorithm
RNN	recurrent neural network
RNNPB	recurrent neural network with parametric bias
RNS	reaction!null-space
ROC	receiver operating curve
ROC	remote!operations centre
ROCCO	robot!construction system for computer integrated construction
ROD	robot!oriented design
ROKVISS	robotics component verification on ISS
ROKVISS	robotics!components verification on the ISS
ROM	run-of-mine
ROM	read-only memory
ROMAN	Robot and Human Interactive Communication
ROS	robot operating system
ROV	remotely operated vehicle
ROV	remotely!operated underwater vehicle

RP	rapid prototyping	SCARA	selective compliance assembly robot arm
RP-VITA	remote presence virtual + independent telemedicine assistant	SCI	spinal cord!injury
RPC	remote procedure call	sci-fi	science fiction
RPI	Rensselaer Polytechnic Institute	SCM	smart composite microstructures
RPS	room positioning system	SCM	soil!contact model
RRSD	Robotics and Remote Systems Division	SD	standard deviation
RRT	rapidly exploring random tree	SDK	standard development kit
RS	Reeds and Shepp	SDK	software development kit
RSJ	Robotics Society of Japan	SDM	shape deposition manufacturing
RSS	Robotics Science and Systems	SDR	software!for distributed robotics
RSTA	reconnaissance, surveillance, and target acquisition	SDV	spatial dynamic voting
RSU	road!side unit	SEA	series elastic actuator
RT	real-time	SEE	standard!end effector

1. Robotics and the Handbook

Bruno Siciliano, Oussama Khatib

Robots! Robots on Mars and in oceans, in hospitals and homes, in factories and schools; robots fighting fires, making goods and products, saving time and lives. Robots today are making a considerable impact on many aspects of modern life, from industrial manufacturing to healthcare, transportation, and exploration of the deep space and sea. Tomorrow, robots will be as pervasive and personal as today's personal computers. This chapter retraces the evolution of this fascinating field from the ancient to the modern times through a number of milestones: from the first automated mechanical artifact (1400 BC) through the establishment of the robot concept in the 1920s, the realization of the first industrial robots in the 1960s, the definition of robotics science and the birth of an active research community in the 1980s, and the expan-

sion towards the challenges of the human world of the twenty-first century. Robotics in its long journey has inspired this handbook which is organized in three layers: the foundations of robotics science; the consolidated methodologies and technologies of robot design, sensing and perception, manipulation and interfaces, mobile and distributed robotics; the advanced applications of field and service robotics, as well as of human-centered and life-like robotics.

1.1 A Brief History of Robotics

The dream to create machines that are skilled and intelligent has been part of humanity from the beginning of time. This dream is now becoming part of our world's striking reality. Since the early civilizations, one of man's greatest ambitions has been to create artifacts in their image. The legend of the Titan Prometheus, who molded humankind from clay, or that of the giant Talus, the bronze slave forged by Hephaestus (3500 BC), testify to this quest in Greek mythology. The Egyptians' oracle statues hiding priests inside (2500 BC) were perhaps the precursor of our modern thinking machines. The clepsydra water clock introduced by the Babylonians (1400 BC) was one of the first automated mechanical artifacts. In the following centuries, human creativity has given rise to a host of devices such as the automaton theatre of Hero of Alexandria (100 AD), the

hydro-powered water-raising and humanoid machines of Al-Jazari (1200), and Leonardo da Vinci's numerous ingenious designs (1500). The development of automata continued to flourish in the eighteen century both in Europe and Asia, with creations such as Jaquet-Droz's family of androids (drawer, musician and writer) and the *karakuri-ningyo* mechanical dolls (tea server and archer).

The robot *concept* was clearly established by those many creative historical realizations. Nonetheless, the emergence of the *physical* robot had to await the advent of its underlying technologies during the course of the twentieth century. In 1920, the term robot – derived from *robota* which means subordinate labour in Slav languages – was first introduced by the Czech playwright Karel Čapek in his play *Rossum's Universal Robots* (R.U.R.). In 1940, the ethics of the interaction

between robots and humans was envisioned to be governed by the well-known three fundamental laws of Isaac Asimov, the Russian science-fiction writer in his novel *Runaround*.

The middle of the twentieth century brought the first explorations of the connection between human intelligence and machines, marking the beginning of an era of fertile research in the field of artificial intelligence (AI). Around that time, the first robots were realized. They benefited from advances in the different technologies of mechanics, controls, computers and electronics. As always, new designs motivate new research and discoveries, which, in turn, lead to enhanced solutions and thus to novel concepts. This virtuous circle over time produced that knowledge and understanding which gave birth to the field of *robotics*, properly referred to as: the science and technology of robots.

The early robots built in the 1960s stemmed from the confluence of two technologies: numerical control machines for precise manufacturing, and teleoperators for remote radioactive material handling. These master-slave arms were designed to duplicate one-to-one the mechanics of the human arm, and had rudimentary control and little perception about the environment. Then, during the mid-to-late twentieth century, the development of integrated circuits, digital computers and miniaturized components enabled computer-controlled robots to be designed and programmed. These robots, termed industrial robots, became essential components in the automation of flexible manufacturing systems in the late 1970s. Further to their wide application in the automotive industry, industrial robots were successfully employed in general industry, such as the metal products, the chemical, the electronics and the food industries. More recently, robots have found new applications outside the factories, in areas such as cleaning, search and rescue, underwater, space, and medical applications.

In the 1980s robotics was defined as the science which studies the *intelligent connection between perception and action*. With reference to this definition, the action of a robotic system is entrusted to a *locomotion* apparatus to move in the environment (wheels, crawlers, legs, propellers) and/or to a *manipulation* apparatus to operate on objects present in the environment (arms, end effectors, artificial hands), where suitable *actuators* animate the mechanical components of the robot. The perception is extracted from the *sensors* providing information on the state of the robot (position

and speed) and its surrounding environment (force and tactile, range and vision). The intelligent connection is entrusted to a *programming, planning and control* architecture which relies on the perception and available *models* of the robot and environment and exploits learning and skill acquisition.

In the 1990s research was boosted by the need to resort to robots to address human safety in hazardous environments (*field robotics*), or to enhance the human operator ability and reduce his/her fatigue (*human augmentation*), or else by the desire to develop products with wide potential markets aimed at improving the quality of life (*service robotics*). A common denominator of such application scenarios was the need to operate in a scarcely structured environment which ultimately requires increased abilities and a higher degree of *autonomy*.

The first video attached to this chapter *Robots – A 50 Year Journey* by Oussama Khatib (2000) shows the development of robotics through the first five decades (VIDEO 805).

By the dawn of the new millennium, robotics has undergone a major transformation in scope and dimensions. This expansion has been brought about by the maturity of the field and the advances in its related technologies. From a largely dominant industrial focus, robotics has been rapidly expanding into the challenges of the human world (*human-centered and life-like robotics*). The new generation of robots is expected to safely and dependably co-habitat with humans in homes, workplaces, and communities, providing support in services, entertainment, education, healthcare, manufacturing, and assistance.

Beyond its impact on physical robots, the body of knowledge robotics has produced is revealing a much wider range of applications reaching across diverse research areas and scientific disciplines, such as: biomechanics, haptics, neurosciences, virtual simulation, animation, surgery, and sensor networks among others. In return, the challenges of the new emerging areas are proving an abundant source of stimulation and insights for the field of robotics. It is indeed at the intersection of disciplines that the most striking advances are expected to happen.

The second video attached to this chapter *Robots – The Journey Continues* by Bruno Siciliano, Oussama Khatib and Torsten Kröger (2015) shows the intensive and vibrating evolution of robotics through the last fifteen years (VIDEO 812).

1.2 The Robotics Community

The dissemination of research results and findings in archival publications and conference presentations has played an important role in the advancement of robotics in the past three decades. The extent of scientific activities in robotics has led to the establishment of professional societies and research networks devoted to the field, which have ultimately contributed to the building of an international robotics community.

In the early 1980s, robotics was entering a new era in its development following the earlier successes in industrial applications. With much energy and excitement, the pioneers of robotics launched a number of initiatives, which came to shape what became our field. The first robotics textbook by Richard Paul *Robot Manipulators: Mathematics, Programming, and Control* appeared in 1981 (MIT Press). A year later, Mike Brady, Richard Paul, and their colleagues established the first journal entirely devoted to robotics, the International Journal of Robotics Research (IJRR), which was followed by the organization in 1983 of the first International Symposium of Robotics Research (ISRR). The intent was to foster the notion of robotics as a distinct scientific field and to create a broad community of robotics. It was in the pursuit of these aims that the International Foundation of Robotics Research (IFRR) was later formally founded in 1986 with the aim of promoting the development of robotics as a science, establishing the theoretical foundations and technology basis for its ever-expanding applications, with emphasis on its potential role to benefit humans.

The year 1984 brought a host of other major developments in robotics with the establishment of the IEEE Robotics and Automation Council (RAC), led by George Saridis, the organization of the first IEEE Conference on Robotics (John Jarvis and Richard Paul) – which became the IEEE International Conference on Robotics and Automation (ICRA) the year after, the launching of the IEEE Journal of Robotics and Automation (George Bekey), and RAC Newsletter (Wesley Snyder). The transformation of the council into the IEEE Robotics and Automation Society (RAS) was formally accomplished in 1989. With the birth of RAS, the IEEE Journal of Robotics and Automation became the IEEE Transactions on Robotics and Automation – which split into the IEEE Transactions on Robotics and the IEEE Transactions on Automation Science and Engineering later in 2004; then, the RAS Newsletter became the IEEE Robotics and Automation Magazine in 1994.

Over the following years, a number of other activities were launched. New conferences such as IEEE/RSJ

International Conference on Intelligent Robots and Systems (IROS 1983), International Conference on Advanced Robotics (ICAR 1983), International Symposium on Experimental Robotics (ISER 1989), Robotics: Science and Systems (RSS 2005), as well as new journals such as Robotica (1983), Journal of Robotic Systems (1984, subsequently Journal of Field Robotics 2006), Robotics and Autonomous Systems (1985), Advanced Robotics (1986), Journal of Intelligent and Robotic Systems (1988), Autonomous Robots (1994), contributed to a further substantial growth of the robotics community.

The year 1991 marked an important novelty into the ICRA flagship conference series with the creation of video proceedings, introduced earlier by Oussama Khatib and Vincent Hayward in ISER 1989. Since then video proceedings attained an important role for dissemination of research work in our robotics community. This media has become an integral part of most archival publications in recent years.

On the other hand, the introduction of graduate programs in robotics in many academic institutions around the world in the last two decades is a clear illustration of the level of maturity reached by robotics as a scientific field. Further to Paul's seminal book, other textbooks were published between the middle 1980s and middle 1990s, such as *Introduction to Robotics: Mechanics and Control* by John Craig (1985), *Robot Analysis and Control* by Harry Asada and Jean-Jacques Slotine (1986), *Robotics: Control, Sensing, Vision, and Intelligence* by King Sun Fu, Rafael González and George Lee (1987), *Robot Dynamics and Control* by Mark Spong and M. Vidyasagar (1989), *Foundation of Robotics* by Tsuneo Yoshikawa (1990), *A Mathematical Introduction to Robotic Manipulation* by Richard Murray, Zexiang Li and Shankar Sastry (1994), and *Modelling and Control of Robot Manipulators* by Lorenzo Sciavicco and Bruno Siciliano (1995).

Engagement with students is essential for the future of the robotics field. Through a joint initiative between IEEE RAS and IFRR, the School of Robotics Science was founded in 2004. Summer schools have rapidly expanded in scope and frequency, covering a wide range of robotics research areas. Such programs are providing students and young researchers with an educational opportunity of the highest scientific level, enabling them to feed and grow their potential to become the top robotics scientists in our community.

Both IEEE RAS and IFRR have constantly promoted research, education, dissemination, and industrial realizations through their own forums and through collaborations with many other organizations

in the robotics community world-wide, including European Robotics Research Network (EURON) – which has recently merged into the European Association of Robotics (euRobotics), International Federation of Robotics (IFR), and Robotics Society of Japan (RSJ). As our field continues to expand and embrace the challenges of operation in the human world, robotics is revealing a much wider range of applications and involving diverse scientific disciplines such as biome-

chanics, neuroscience, haptics, animation, surgery, and sensor networks among others. Today, new communities of researchers and developers are forming, with growing connections to the core of robotics research. A strategic goal for our community is one of outreach and scientific cooperation across all regions and organizations. Our common endeavor as roboticists to reach this goal certainly holds the promise of exciting advances toward new frontiers.

1.3 This Handbook

The intensive stream of robotics research documented in the literature culminates into this unique reference, which aims at collecting in one self-contained volume the most significant achievements of our international robotics community. The *Springer Handbook of Robotics* presents a full coverage of the field from its foundations, through the research areas, up to the new emerging applications of robotics. Accordingly, the material is organized in three logical layers reflecting the historical development of the field, as illustrated in Fig. 1.1.

The foundations of robotics science, laid down in the first layer (Part A with its 14 chapters), address the theory of robot mechanics, sensing, planning, and control. The consolidated methodologies and technologies of robot design (Part B with its 12 chapters), sensing and perception (Part C with its 8 chapters), manipulation and interfaces (Part D with its 9 chapters) and mobile and distributed robotics (Part E with its 9 chapters) are presented in the second layer. The third layer

is devoted to advanced applications, such as in field and service robotics (Part F with its 13 chapters) and human-centered and life-like robotics (Part G with its 14 chapters).

Part A presents the fundamental principles and methods that are used to model, design, and control a robotic system. All of the foundational topics are included in this part: kinematics, dynamics, mechanisms and actuation, sensing and estimation, model identification, motion planning, motion control, force control, redundant robots, robots with flexible elements, robotic systems architectures and programming, behaviour-based systems, AI reasoning methods for robotics, robot learning. A chapter is devoted to each of these topics. The topics are expanded and applied to specific robotic structures and systems in subsequent parts.

Part B is concerned with the design of various robotic systems. Some of the obvious mechanical structures that come to mind are arms, legs, wheels and hands; to this list can be added robots in the air

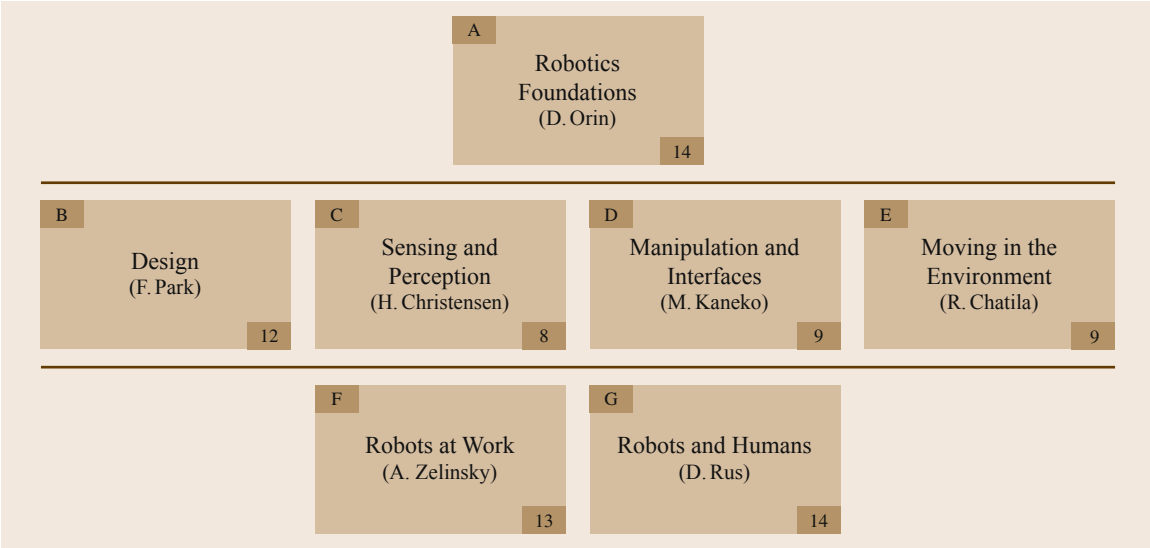

Fig. 1.1 Organization of the handbook

and subsea, as well as robot structures at the micro and nano scales. With a separate chapter devoted to design and evaluation performance, the chapters in this part successively examine limbed systems, parallel mechanisms, robot hands, snake-like and continuum robots, novel actuators for soft robotics, modular robots, biomimetic robots, wheeled robots, underwater robots, flying robots, and micro/nano robots.

Part C covers different sensory modalities and integration of sensor data across space and time to generate models of robots and the external environment. Robotics is the intelligent coupling of perception and action and as such *Part C* complements *Part B* to build systems. This part of the handbook covers sensing across contact, proprioception and exteroception. The main sensing modalities such as force and tactile sensing, inertial sensing, global positioning system (GPS) and odometry, sonar sensing, range sensing, three-dimensional (3-D) vision for navigation and grasping visual object class recognition, and visual servoing are presented. Both basic sensor models, sensor data processing and associated representations are covered. Finally, a chapter on multisensor data fusion introduces the mathematical tools needed for integration of sensor information across space and time.

Part D is concerned with interaction between robots and objects, or between humans and robots. Manipulation is supposed to handle an object through direct contact by arms or fingers or just a pusher, while interfaces are supposed to make either direct or indirect interaction between humans and robots. For enhancing dexterity in robot manipulation, motion for manipulation tasks, contact modelling and manipulation, grasping, cooperative manipulation, mobility and manipulation, active manipulation for perception are addressed in the first half of this part. For achieving a skilful manipulation or power increase in a human–robot system, haptics, telerobotics, and networked robots are discussed in the second half of *Part D*.

Part E covers a wide span of topics concerning the motion of robots in the environment. At first this part addresses world modelling, simultaneous localization and mapping, motion planning and obstacle avoidance. Then the modelling and control issues of legged robots, wheeled mobile robots, robots on rough terrain, underwater robots, and aerial robots are dealt with. This part completes *Part A* on foundations in the context of mobile robotics, and given the role of perception, is closely related to *Part C* on sensing. In addition, multiple mobile robot systems are discussed.

Part F covers topics related to creating field and service application-based robots that operate in all types of environments. This includes applications ranging from industrial robots to robotics competitions and chal-

lenges, through a diverse array of robotics applications: space, agriculture and forestry, construction, hazardous applications, mining, disaster scenarios, intelligent vehicles, medical and computer-integrated surgery, rehabilitation and health-care, domestic environments. This part of the handbook, which draws on *Parts A, B, C, D* and *E*, describes how robots can be put to work.

Part G covers topics related to creating robots that operate in human-centered environments. These include humanoids, human motion reconstruction, physical human–robot interaction, human robot augmentation, cognitive human–robot interaction, social robotics, socially assistive robotics, learning from humans, biologically-inspired robotics, evolutionary robotics, neurobotics, and perceptual robotics. The part concludes with the use of robotics for education, and the socio-ethical implications of robots.

Each part is accompanied by a video which illustrates the main concepts and the underlying challenges in common to the chapters in the part, while topical videos related to the specific contents of each chapter can be accessed through the web site of the multimedia contents associated with the handbook <http://handbookofrobotics.org/>.

The handbook has been conceived to provide a valuable resource not only for robotics experts, but also for newcomers to this expanding field, e.g., engineers, medical doctors, computer scientists, and designers. In particular, it is important to underline the tutorial value of *Part A* to graduate students and post-docs, the research value of *Parts B* to *E* for a wider coverage of research in robotics, and the added value of *Parts F* and *G* to engineers and scientists interested in new applications.

The contents of the various chapters have been inspired by a classic cut, i.e., avoiding the inclusion of on-going or not well-established methods. An objective perspective has been taken, while covering multiple approaches, with the goal of ensuring a high archival value to the handbook. Each chapter is preceded by a short summary, and an introductory section providing the state of the art in the area. The core sections are developed at a tutorial level. Lengthy mathematical derivations have been avoided whenever possible, while the equations, tables, and algorithms are illustrated in ready-to-use form. The final section of the chapter provides conclusions and topics for further reading. From the foundations to the social and ethical implications of robotics, the eighty chapters of the handbook provide a comprehensive collection of five decades of progress in robotics. This sum is a testimony to the level of accomplishments in our field, and a premise of further advances towards new frontiers of robotics.

The chapters contained in **Part A**, Robotics Foundations, present the fundamental principles and methods that are used to develop a robotic system. In order to perform the tasks that are envisioned for robots, many challenging problems have been uncovered in kinematics, dynamics, design, actuation, sensing, modeling, motion planning, control, programming, decision-making, task planning, and learning. Robots with redundant kinematic degrees of freedom or with flexible elements add to the complexity of these systems. The chapters in this part address the basic issues in each of these areas.

Some of the basic problems in robotics are outlined as follows. Robots often consist of a large number of degrees of freedom so that they can provide the rich set of three-dimensional (3-D) motions that may be required for a range of tasks. The kinematic and dynamic relationships between the joint actuators' motion and torques, and the desired motion and force for a task can be very complex. The design of the link and joint structures, as well as the actuation, to achieve the desired performance is also challenging.

The robot is a nonlinear, coupled system which is difficult to model and control because of its complex dynamics. Kinematic redundancy and flexible elements in the robots increase this complexity. The problem is exacerbated when the environment is unstructured, and often sophisticated sensing and estimation techniques are required.

In addition to control of the motion, control of the interaction forces between the robot and environment is needed when manipulating objects or interacting with humans. A fundamental robotics task is to plan collision-free motion for complex bodies from a start to a goal position among a collection of obstacles, and this can become an intractable computational problem.

In order to achieve some of the intelligence ascribed to humans, robots will need to be equipped with sophisticated action planners that employ symbolic reasoning to move in dynamic, partially known environments. In other scenarios, robots need to execute behaviors that take advantage of dynamic interactions with the environment rather than rely solely on explicit reasoning and planning. Robot software architectures also have special needs because of all of these requirements. Robot learning will be necessary to generate actions and control for ever-changing task requirements and environments, in order to achieve the level of autonomy envisioned.

While the basic issues outlined in the previous paragraphs are addressed in this part, more depth can be

found in other parts of the handbook. The kinematics, dynamics, mechanical design, and control principles and methods introduced in this part can be applied to robotic structures made up of arms, hands, and legs (Part B) as well as manipulators (Part D), wheeled and other mobile robots (Part E), and field and service robots (Part F). Force control is especially important for manipulators and their interfaces (Part D). The basic sensing and estimation techniques presented here are expanded and applied to specific sensing modalities in Part C. Motion planning is an important aspect of manipulation (Part D) and mobile robots moving in the environment (Part E). Robotic systems architectures, behavior-based systems, artificial intelligence (AI) reasoning methods, and robot learning are particularly important in mobile robots moving in the environment (Part E) and robots interacting with humans (Part G).

With this overview of Part A, we now provide a brief synopsis of each chapter:

Chapter 2, Kinematics, provides a number of representations and conventions to describe the motion of the bodies in a robotic mechanism. These include rotation matrices, Euler angles, quaternions, homogeneous transformations, screw transformations, matrix exponential parameterization, and Plücker coordinates. Representations of the kinematics of all common joint types are provided, along with a modified form of the Denavit–Hartenberg convention. These representational tools are applied to compute the workspace, the forward and inverse kinematics, the forward and inverse instantaneous kinematics, Jacobian, and the static wrench transmission.

Chapter 3, Dynamics, presents the dynamic equations of motion which provide the relationships between actuation and contact forces acting on robot mechanisms, and the acceleration and motion trajectories that result. Efficient algorithms are provided for important dynamics computations which include inverse dynamics, forward dynamics, the joint-space inertia matrix, and the operational-space inertia matrix. The algorithms may be applied to fixed-base robots, mobile robots, and parallel robot mechanisms. Compact formulation of the algorithms results from using six-dimensional (6-D) spatial notation to describe rigid-body velocity, acceleration, inertia, etc.

Chapter 4, Mechanisms and Actuation, focuses on the principles that guide the design and construction of robotic systems. The kinematic equations and Jacobian are used to characterize the work envelope and mechanical advantage, and guide the selection of the robot's size and joint arrangement. The design of both serial and parallel robots is addressed. Practical consideration

is given to the design of the link and joint structures along with selection of the actuators and transmission drives to power the movement. Robot performance in terms of speed, acceleration, repeatability, and other measures is also addressed.

Chapter 5, Sensing and Estimation, provides a brief overview of common sensing methods and estimation techniques that have found broad applicability in robotics. These provide information about the state of the environment and robot system. The presentation is structured according to a perception process model that includes sensing, feature extraction, data association, parameter estimation and model integration. Several common sensing modalities are introduced and characterized. Methods for estimation in linear and nonlinear systems are discussed, including statistical estimation, the Kalman filter, and sample-based methods. The several common representations for estimation are also introduced.

Chapter 6, Model Identification, discusses methods for determining the kinematic and inertial parameters of robot manipulators. For kinematic calibration, the primary aim is to identify the geometric Denavit–Hartenberg parameters or equivalent, typically by sensing a combination of joint and endpoint positions. Inertial parameters in turn are estimated through the execution of a trajectory while additionally sensing one or more components of joint forces or torques. The chapter is organized such that both kinematic and inertial parameter identification are cast into a common framework of least-squares parameter estimation: common features relating to the identifiability of the parameters, adequacy of the measurement sets, and numerical robustness are identified and emphasized for both the kinematic and inertial parameters.

Chapter 7, Motion Planning, addresses the fundamental robotics task to plan collision-free motion for complex bodies from a start to a goal position among a collection of obstacles. The basic geometric path planning problem (Piano Mover’s problem) is introduced, but the focus of the chapter is on sampling-based planning methods because of their generally wider applicability. Planning with differential constraints is considered and is important for wheeled mobile robots. Extensions and variations to the basic motion planning problem, as well as advanced issues, are discussed at the end of the chapter.

Chapter 8, Motion Control, focuses on the control of the motion of a rigid manipulator. The main challenges addressed are the complexity of the nonlinear, coupled dynamics and the model structural uncertainties. The chapter discusses topics ranging

from independent-joint control and **PID** (proportional–integral–derivative) control to computed-torque control to manage the complex dynamics. Operational space (or task space) control is presented, and this is needed for control of tasks such as those associated with the end-effector. Adaptive and robust control are discussed to address the problems related to the uncertainties in the system. Other topics presented include trajectory generation, digital implementation, and learning control.

Chapter 9, Force Control, focuses on the control of the interaction forces between a robotic system and its environment. The chapter groups interaction control in two categories: indirect and direct force control, which achieve the control without (indirect) or with (direct) explicit closure of a force feedback loop. Impedance control and hybrid force/motion control are examples of each, respectively. The fundamental problem of interaction tasks modeling is presented to provide the basis for the force control schemes.

Chapter 10, Redundant Robots, addresses the motion generation and control of manipulators with redundant kinematic degrees of freedom. Kinematic redundancy affords a robot with an increased level of dexterity that may be used to, e.g., avoid singularities, joint limits and workspace obstacles, and also to minimize joint torques, energy, or other suitable performance criteria. The chapter discusses inverse kinematic redundancy resolution schemes which are arranged in two main categories, namely those based on the optimization of suitable performance criteria and those relying on the augmentation of the task space. The use of kinematic redundancy for fault tolerance is also analyzed.

Chapter 11, Robots with Flexible Elements, addresses the dynamic modeling and control of robots with flexibility in the joints and links. Because the control methods developed to compensate for joint versus link flexibility are structurally different, the chapter is organized such that these two types of flexibility are examined independently. The methods, however, can be extended to the case when both joint and link flexibilities are present, possibly even dynamically interacting at the same time. The chapter also examines the typical sources of flexibility in industrial robots.

Chapter 12, Robotic Systems Architectures and Programming, presents the software architectures and supporting programming tools and environments that have been developed for robotic systems. Robot architectures have special needs because of the requirements of the robot to interact asynchronously, in real time, with an uncertain, often dynamic, environment. The chapter discusses the major types of architectural com-

ponents for a layered robot control architecture – behavioral control, executives, and task planners – along with the commonly used techniques for interconnecting these components.

Chapter 13, Behavior-Based Systems, describes a control methodology aimed at situated robots operating in unconstrained, challenging, and dynamic conditions in the real world. Distributed behaviors are used as the underlying building blocks, allowing behavior-based systems to take advantage of dynamic interactions with the environment rather than rely solely on explicit reasoning and planning. The focus of the chapter is to provide the basic principles of behavior-based systems and their use in autonomous control problems and applications. The chapter presents several different classes of learning methods, but in all cases behaviors are used as the underlying building blocks for the learning process.

Chapter 14, AI Reasoning Methods for Robotics, sketches the main robotics-relevant topics of symbol-based AI reasoning. Reasoning on a mobile robot is especially challenging because of its dynamic, partially known environment. This chapter describes basic methods of knowledge representation and inference, covering both logic- and probability-based approaches. Results for several types of practical, robotics-related reasoning tasks are given, with an emphasis on temporal and spatial reasoning. Plan-based robot control is

described in some detail, as it is a particularly obvious form of employing reasoning to the end of improving robot action.

Chapter 15, Robot Learning, surveys work in machine learning for techniques that are used for learning control and behavior generation in robots. In the future, robots will no longer be used to only execute the same task thousands of times, but rather they will be faced with thousands of different tasks that rarely repeat in an ever-changing environment. Robot learning will be necessary to achieve the high degree of autonomy envisioned. This chapter focuses on the core robot learning approaches capable of learning action generation and control, and in particular, techniques for model learning and reinforcement learning.

Part A presents the fundamental principles and methods that are used to model, design, and control a robotic system. All of the foundational topics are included in this part: kinematics, dynamics, mechanisms and actuation, sensing and estimation, model identification, motion planning, motion control, force control, redundant robots, robots with flexible elements, robotic systems architectures and programming, behavior-based systems, AI reasoning methods for robotics, and robot learning. A chapter is devoted to each of these topics. The topics are expanded and applied to specific robotic structures and systems in subsequent parts.

2. Kinematics

Kenneth J. Waldron, James Schmiedeler

Kinematics pertains to the motion of bodies in a robotic mechanism without regard to the forces/torques that cause the motion. Since robotic mechanisms are by their very essence designed for motion, kinematics is the most fundamental aspect of robot design, analysis, control, and simulation. The robotics community has focused on efficiently applying different representations of position and orientation and their derivatives with respect to time to solve foundational kinematics problems.

This chapter will present the most useful representations of the position and orientation of a body in space, the kinematics of the joints most commonly found in robotic mechanisms, and a convenient convention for representing the geometry of robotic mechanisms. These representational tools will be applied to compute the *workspace*, the *forward* and *inverse kinematics*, the *forward* and *inverse instantaneous kinematics*, and the *static wrench transmission* of a robotic mechanism. For brevity, the focus will be on algorithms applicable to open-chain mechanisms.

The goal of this chapter is to provide the reader with general tools in tabulated form and a broader overview of algorithms that can be applied together to solve kinematics problems pertaining to a particular robotic mechanism.

2.1 Overview

Unless explicitly stated otherwise, robotic mechanisms are systems of rigid bodies connected by joints. The position and orientation of a rigid body in space are collectively termed the *pose*. Therefore, robot kinematics describes the pose, velocity, acceleration, and all higher-order derivatives of the pose of the bodies that comprise a mechanism. Since kinematics does not address the forces/torques that induce motion, this chapter focuses on describing pose and velocity. These descriptions are foundational elements of dynamics (Chap. 3), motion planning (Chap. 7), and motion control (Chap. 8) algorithms.

Among the many possible topologies in which systems of bodies can be connected, two of particular importance in robotics are serial chains and fully parallel mechanisms. A serial chain is a system of rigid bodies in which each member is connected to

two others, except for the first and last members that are each connected to only one other member. A fully parallel mechanism is one in which there are two members that are connected together by multiple chains of other members and joints. In practice, each of these chains is often itself a serial chain. This chapter focuses almost exclusively on algorithms applicable to serial chains. Parallel mechanisms are dealt with in more detail in Chap. 18. Another important topology is the tree structure, which is similar to a serial chain in that it has no closed loops, but differs from a serial chain in that each member might have multiple members connected to it, forming multiple *branches*. A serial chain is actually just a special case of a tree structure with no branches. Tree structures are addressed in greater depth in Chap. 3.

2.2 Position and Orientation Representation

Spatial, rigid-body kinematics can be viewed as a comparative study of different ways of representing the pose of a body. Translations and rotations, referred to in combination as rigid-body displacements, are also expressed with these representations. No one approach is optimal for all purposes, but the advantages of each can be leveraged appropriately to facilitate the solution of different problems.

The minimum number of coordinates required to locate a body in Euclidean space is six. Many representations of spatial pose employ sets with superabundant coordinates in which auxiliary relationships exist among the coordinates. The number of independent auxiliary relationships is the difference between the number of coordinates in the set and six.

This chapter and those that follow it make frequent use of *coordinate frames* or simply *frames*. A coordinate frame i consists of an origin, denoted O_i , and a triad of mutually orthogonal basis vectors, denoted $(\hat{x}_i, \hat{y}_i, \hat{z}_i)$, that are all fixed within a particular body. The pose of a body will always be expressed relative to some other body, so it can be expressed as the pose of one coordinate frame relative to another. Similarly, rigid-body displacements can be expressed as displacements between two coordinate frames, one of which may be referred to as *moving*, while the other may be referred to as *fixed*. This indicates that the observer is located in a stationary position within the fixed frame, not that there exists any absolutely fixed frame.

2.2.1 Position and Displacement

The position of the origin of coordinate frame i relative to coordinate frame j can be denoted by the 3×1 vector

$${}^j\mathbf{p}_i = \begin{pmatrix} {}^j p_i^x \\ {}^j p_i^y \\ {}^j p_i^z \end{pmatrix}.$$

The components of this vector are the Cartesian coordinates of O_i in the j frame, which are the projections of the vector ${}^j\mathbf{p}_i$ onto the corresponding axes. The vector components could also be expressed as the spherical or cylindrical coordinates of O_i in the j frame. Such representations have advantages for analysis of robotic mechanisms including spherical and cylindrical joints.

A translation is a displacement in which no point in the rigid body remains in its initial position and all straight lines in the rigid body remain parallel to their initial orientations. (The points and lines are not necessarily contained within the boundaries of the finite rigid body, but rather, any point or line in space can be taken to be rigidly fixed in a body.) The translation of a body in space can be represented by the combination of its positions prior to and following the translation. Conversely, the position of a body can be represented as a translation that takes the body from a starting position (in which the coordinate frame fixed to the body coincides with the fixed coordinate frame) to the current position (in which the two frames are not coincident).

Thus, any representation of position can be used to create a representation of displacement, and vice versa.

2.2.2 Orientation and Rotation

There is significantly greater breadth in the representation of orientation than in that of position. This section does not include an exhaustive summary, but focuses on the representations most commonly applied to robotic mechanisms.

A rotation is a displacement in which at least one point in the rigid body remains in its initial position and not all lines in the body remain parallel to their initial orientations. For example, a body in a circular orbit rotates about an axis through the center of its circular path, and every point on the axis of rotation is a point in the body that remains in its initial position. As in the case of position and translation, any representation of orientation can be used to create a representation of rotation, and vice versa.

Rotation Matrices

The orientation of coordinate frame i relative to coordinate frame j can be denoted by expressing the basis vectors $(\hat{x}_i \hat{y}_i \hat{z}_i)$ in terms of the basis vectors $(\hat{x}_j \hat{y}_j \hat{z}_j)$. This yields $({}^j\hat{x}_i {}^j\hat{y}_i {}^j\hat{z}_i)$, which when written together as a 3×3 matrix is known as the rotation matrix. The components of ${}^j\mathbf{R}_i$ are the dot products of the basis vectors of the two coordinate frames.

$${}^j\mathbf{R}_i = \begin{pmatrix} \hat{x}_i \cdot \hat{x}_j & \hat{y}_i \cdot \hat{x}_j & \hat{z}_i \cdot \hat{x}_j \\ \hat{x}_i \cdot \hat{y}_j & \hat{y}_i \cdot \hat{y}_j & \hat{z}_i \cdot \hat{y}_j \\ \hat{x}_i \cdot \hat{z}_j & \hat{y}_i \cdot \hat{z}_j & \hat{z}_i \cdot \hat{z}_j \end{pmatrix}. \quad (2.1)$$

Because the basis vectors are unit vectors and the dot product of any two unit vectors is the cosine of the angle between them, the components are commonly referred to as direction cosines.

An elementary rotation of frame i about the \hat{z}_j axis through an angle θ is

$$\mathbf{R}_Z(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (2.2)$$

while the same rotation about the \hat{y}_j axis is

$$\mathbf{R}_Y(\theta) = \begin{pmatrix} \cos \theta & 0 & \sin \theta \\ 0 & 1 & 0 \\ -\sin \theta & 0 & \cos \theta \end{pmatrix}, \quad (2.3)$$

and about the \hat{x}_j axis is

$$\mathbf{R}_X(\theta) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}. \quad (2.4)$$

Rotation matrices are combined through simple matrix multiplication such that the orientation of frame i relative to frame k can be expressed as

$${}^k\mathbf{R}_i = {}^k\mathbf{R}_j {}^j\mathbf{R}_i.$$

The rotation matrix ${}^j\mathbf{R}_i$ contains nine elements, while only three parameters are required to define the orientation of a body in space. Therefore, six auxiliary relationships exist among the elements of the matrix. Because the basis vectors of coordinate frame i are mutually orthonormal, as are the basis vectors of coordinate frame j , the columns of ${}^j\mathbf{R}_i$ formed from the dot products of these vectors are also mutually orthonormal. A matrix composed of mutually orthonormal vectors is known as an orthogonal matrix and has the property that its inverse is simply its transpose. This property provides the six auxiliary relationships. Three require the column vectors to have unit length, and three require the column vectors to be mutually orthogonal. Alternatively, the orthogonality of the rotation matrix can be seen by considering the frames in reverse order. The orientation of coordinate frame j relative to coordinate frame i is the rotation matrix ${}^i\mathbf{R}_j$ whose rows are clearly the columns of the matrix ${}^j\mathbf{R}_i$.

In summary, ${}^j\mathbf{R}_i$ is the rotation matrix that transforms a vector expressed in coordinate frame i to a vector expressed in coordinate frame j . It provides a representation of the orientation of frame i relative to j and thus, can be a representation of rotation from frame i to frame j . Table 2.1 lists the equivalent rotation matrices for the other representations of orientation listed in this section. Table 2.2 contains the conversions from a known rotation matrix to these other representations.

Euler Angles

For a minimal representation, the orientation of coordinate frame i relative to coordinate frame j can be denoted as a vector of three angles $(\alpha, \beta, \gamma)^T$. These angles are known as Euler angles when each represents a rotation about an axis of a moving coordinate frame. In this way, the location of the axis of each successive rotation depends upon the preceding rotation(s), so the order of the rotations must accompany the three angles to define the orientation. For example, the symbols $(\alpha, \beta, \gamma)^T$ are used throughout this handbook to indicate Z-Y-X Euler angles. Taking the moving frame i and the fixed frame j to be initially coincident, α is the rotation about the \hat{z} axis of frame i , β is the rotation about the rotated \hat{y} axis of frame i , and finally, γ is the rotation about the twice rotated \hat{x} axis of frame i . The equivalent rotation matrix ${}^j\mathbf{R}_i$ is given in Table 2.1. Z-Y-Z and X-Z-Z Euler angles are other commonly used con-

Table 2.1 Equivalent rotation matrices for various representations of orientation, with abbreviations $c_\theta := \cos \theta$, $s_\theta := \sin \theta$, and $v_\theta := 1 - \cos \theta$

Z-Y-X Euler angles $(\alpha, \beta, \gamma)^T$	${}^j\mathbf{R}_i = \begin{pmatrix} c_\alpha c_\beta & c_\alpha s_\beta s_\gamma - s_\alpha c_\gamma & c_\alpha s_\beta c_\gamma + s_\alpha s_\gamma \\ s_\alpha c_\beta & s_\alpha s_\beta s_\gamma + c_\alpha c_\gamma & s_\alpha s_\beta c_\gamma - c_\alpha s_\gamma \\ -s_\beta & c_\beta s_\gamma & c_\beta c_\gamma \end{pmatrix}$
X-Y-Z fixed angles $(\psi, \theta, \phi)^T$	${}^j\mathbf{R}_i = \begin{pmatrix} c_\phi c_\theta & c_\phi s_\theta s_\psi - s_\phi c_\psi & c_\phi s_\theta c_\psi + s_\phi s_\psi \\ s_\phi c_\theta & s_\phi s_\theta s_\psi + c_\phi c_\psi & s_\phi s_\theta c_\psi - c_\phi s_\psi \\ -s_\theta & c_\theta s_\psi & c_\theta c_\psi \end{pmatrix}$
Angle-axis $\theta \hat{\mathbf{w}}$	${}^j\mathbf{R}_i = \begin{pmatrix} w_x^2 v_\theta + c_\theta & w_x w_y v_\theta - w_z s_\theta & w_x w_z v_\theta + w_y s_\theta \\ w_x w_y v_\theta + w_z s_\theta & w_y^2 v_\theta + c_\theta & w_y w_z v_\theta - w_x s_\theta \\ w_x w_z v_\theta - w_y s_\theta & w_y w_z v_\theta + w_x s_\theta & w_z^2 v_\theta + c_\theta \end{pmatrix}$
Unit quaternions $(\epsilon_0 \ \epsilon_1 \ \epsilon_2 \ \epsilon_3)^T$	${}^j\mathbf{R}_i = \begin{pmatrix} 1-2(\epsilon_2^2 + \epsilon_3^2) & 2(\epsilon_1\epsilon_2 - \epsilon_0\epsilon_3) & 2(\epsilon_1\epsilon_3 + \epsilon_0\epsilon_2) \\ 2(\epsilon_1\epsilon_2 + \epsilon_0\epsilon_3) & 1-2(\epsilon_1^2 + \epsilon_3^2) & 2(\epsilon_2\epsilon_3 - \epsilon_0\epsilon_1) \\ 2(\epsilon_1\epsilon_3 - \epsilon_0\epsilon_2) & 2(\epsilon_2\epsilon_3 + \epsilon_0\epsilon_1) & 1-2(\epsilon_1^2 + \epsilon_2^2) \end{pmatrix}$

ventions from among the 12 different possible orders of rotations.

Regardless of the order of rotations, an Euler angle representation of orientation always exhibits a singularity when the first and last rotations both occur about the

Table 2.2 Conversions from a rotation matrix to various representations of orientation

Rotation matrix:
${}^j\mathbf{R}_i = \begin{pmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{pmatrix}$
Z-Y-X Euler angles $(\alpha, \beta, \gamma)^T$:
$\beta = \text{Atan2}\left(-r_{31}, \sqrt{r_{11}^2 + r_{21}^2}\right)$
$\alpha = \text{Atan2}\left(\frac{r_{21}}{\cos \beta}, \frac{r_{11}}{\cos \beta}\right)$
$\gamma = \text{Atan2}\left(\frac{r_{32}}{\cos \beta}, \frac{r_{33}}{\cos \beta}\right)$
X-Y-Z fixed angles $(\psi, \theta, \phi)^T$:
$\theta = \text{Atan2}\left(-r_{31}, \sqrt{r_{11}^2 + r_{21}^2}\right)$
$\psi = \text{Atan2}\left(\frac{r_{21}}{\cos \theta}, \frac{r_{11}}{\cos \theta}\right)$
$\phi = \text{Atan2}\left(\frac{r_{32}}{\cos \theta}, \frac{r_{33}}{\cos \theta}\right)$
Angle axis $\theta \hat{\mathbf{w}}$:
$\theta = \cos^{-1}\left(\frac{r_{11} + r_{22} + r_{33} - 1}{2}\right)$
$\hat{\mathbf{w}} = \frac{1}{2\sin \theta} \begin{pmatrix} r_{32} - r_{23} \\ r_{13} - r_{31} \\ r_{21} - r_{12} \end{pmatrix}$
Unit quaternions $(\epsilon_0 \ \epsilon_1 \ \epsilon_2 \ \epsilon_3)^T$:
$\epsilon_0 = \frac{1}{2}\sqrt{1 + r_{11} + r_{22} + r_{33}}$
$\epsilon_1 = \frac{r_{32} - r_{23}}{4\epsilon_0}$
$\epsilon_2 = \frac{r_{13} - r_{31}}{4\epsilon_0}$
$\epsilon_3 = \frac{r_{21} - r_{12}}{4\epsilon_0}$

same axis. This can be readily seen in the second block of Table 2.2 wherein the angles α and γ are undefined when $\beta = \pm 90^\circ$. (For Z-Y-Z and Z-X-Z Euler angles, the singularity occurs when the second rotation is 0° or 180° .) This creates a problem in relating the angular velocity vector of a body to the time derivatives of Euler angles, which somewhat limits their usefulness in modeling robotic systems. This velocity relationship for Z-Y-X Euler angles is

$$\begin{pmatrix} \dot{\alpha} \\ \dot{\beta} \\ \dot{\gamma} \end{pmatrix} = \frac{1}{\cos \beta} \begin{pmatrix} 0 & \sin \gamma & \cos \gamma \\ 0 & \cos \gamma \cos \beta & -\sin \gamma \cos \beta \\ \cos \beta & \sin \gamma \sin \beta & \cos \gamma \sin \beta \end{pmatrix} \begin{pmatrix} \omega_x \\ \omega_y \\ \omega_z \end{pmatrix}, \quad (2.5)$$

where $(\omega_x, \omega_y, \omega_z)^T = {}^i\boldsymbol{\omega}_i$ is given in moving frame i . In some circumstances, the inverse of this relationship may be required.

$$\begin{pmatrix} \omega_x \\ \omega_y \\ \omega_z \end{pmatrix} = \begin{pmatrix} -\sin \beta & 0 & 1 \\ \cos \beta \sin \gamma & \cos \gamma & 0 \\ \cos \beta \cos \gamma & -\sin \gamma & 0 \end{pmatrix} \begin{pmatrix} \dot{\alpha} \\ \dot{\beta} \\ \dot{\gamma} \end{pmatrix}. \quad (2.6)$$

Fixed Angles

A vector of three angles can also denote the orientation of coordinate frame i relative to coordinate frame j when each angle represents a rotation about an axis of a fixed frame. Appropriately, such angles are referred to as fixed angles, and the order of the rotations must again accompany the angles to define the orientation. X-Y-Z fixed angles, denoted here as $(\psi, \theta, \phi)^T$, are a common convention from among the, again, 12 different possible orders of rotations. Taking the moving frame i and

the fixed frame j to be initially coincident, ψ is the yaw rotation about the fixed \hat{x}_j axis, θ is the pitch rotation about the fixed \hat{y}_j axis, and ϕ is the roll rotation about the fixed \hat{z}_j axis. As can be seen by comparing the respective equivalent rotation matrices in Table 2.1 and the respective conversions in Table 2.2, a set of X - Y - Z fixed angles is exactly equivalent to the same set of Z - Y - X Euler angles ($\alpha = \phi$, $\beta = \theta$, and $\gamma = \psi$). This result holds in general such that three rotations about the three axes of a fixed frame define the same orientation as the same three rotations taken in the opposite order about the three axes of a moving frame. Likewise, all fixed-angle representations of orientations suffer from the singularity discussed for Euler angles. Also, the relationship between the time derivatives of fixed angles and the angular velocity vector is similar to the relationship for Euler angles.

Angle-Axis

A single angle θ in combination with a unit vector \hat{w} can also denote the orientation of coordinate frame i relative to coordinate frame j . In this case, frame i is rotated through the angle θ about an axis defined by the vector $\hat{w} = (w_x \ w_y \ w_z)^T$ relative to frame j . The vector \hat{w} is sometimes referred to as the equivalent axis of a finite rotation. The angle-axis representation, typically written as either $\theta \hat{w}$ or $(\theta w_x \ \theta w_y \ \theta w_z)^T$, is superabundant by one because it contains four parameters. The auxiliary relationship that resolves this is the unit magnitude of vector \hat{w} . Even with this auxiliary relationship, the angle-axis representation is not unique because rotation through an angle of $-\theta$ about $-\hat{w}$ is equivalent to a rotation through θ about \hat{w} . Table 2.3 contains the conversions from the angle-axis representation to unit quaternions and vice versa. The conversions from these two representations to Euler angles or fixed angles can be easily found by using

Table 2.3 Conversions from angle-axis to unit quaternion representations of orientation and vice versa

Angle-axis $\theta \hat{w}$ to unit quaternion $(\epsilon_0 \ \epsilon_1 \ \epsilon_2 \ \epsilon_3)^T$:

$$\epsilon_0 = \cos \frac{\theta}{2}$$

$$\epsilon_1 = w_x \sin \frac{\theta}{2}$$

$$\epsilon_2 = w_y \sin \frac{\theta}{2}$$

$$\epsilon_3 = w_z \sin \frac{\theta}{2}$$

Unit quaternion $(\epsilon_0 \ \epsilon_1 \ \epsilon_2 \ \epsilon_3)^T$ to angle-axis $\theta \hat{w}$:

$$\theta = 2 \cos^{-1} \epsilon_0$$

$$w_x = \frac{\epsilon_1}{\sin \frac{\theta}{2}}$$

$$w_y = \frac{\epsilon_2}{\sin \frac{\theta}{2}}$$

$$w_z = \frac{\epsilon_3}{\sin \frac{\theta}{2}}$$

the conversions in Table 2.2 in conjunction with the equivalent rotation matrices in Table 2.1. Velocity relationships are more easily dealt with using the closely related quaternion representation.

Quaternions

The quaternion representation of orientation due to *Hamilton* [2.1], while largely superseded by the simpler vector representations of *Gibbs* [2.2] and *Graßmann* [2.3], is extremely useful for problems in robotics that result in representational singularities in the vector/matrix notation [2.4]. Quaternions do not suffer from singularities as Euler and fixed angles do.

A quaternion ϵ is defined to have the form

$$\epsilon = \epsilon_0 + \epsilon_1 i + \epsilon_2 j + \epsilon_3 k,$$

where the components ϵ_0 , ϵ_1 , ϵ_2 , and ϵ_3 are scalars, sometimes referred to as Euler parameters, and i , j , and k are operators. The operators are defined to satisfy the following combinatory rules

$$ii = jj = kk = -1,$$

$$ij = k, jk = i, ki = j,$$

$$ji = -k, kj = -i, ik = -j.$$

Two quaternions are added by adding the respective components separately, so the operators act as separators. The null element for addition is the quaternion $\mathbf{0} = 0 + 0i + 0j + 0k$, and quaternion sums are associative, commutative, and distributive. The null element for multiplication is $\mathbf{I} = 1 + 0i + 0j + 0k$, as can be seen using $\mathbf{I}\epsilon = \epsilon$ for any quaternion ϵ . Quaternion products are associative and distributive, but not commutative, and following the conventions of the operators and addition, have the form

$$\begin{aligned} ab &= a_0 b_0 - a_1 b_1 - a_2 b_2 - a_3 b_3 \\ &+ (a_0 b_1 + a_1 b_0 + a_2 b_3 - a_3 b_2) i \\ &+ (a_0 b_2 + a_2 b_0 + a_3 b_1 - a_1 b_3) j \\ &+ (a_0 b_3 + a_3 b_0 + a_1 b_2 - a_2 b_1) k. \end{aligned} \quad (2.7)$$

It is convenient to define the conjugate of a quaternion

$$\tilde{\epsilon} = \epsilon_0 - \epsilon_1 i - \epsilon_2 j - \epsilon_3 k,$$

so that

$$\epsilon \tilde{\epsilon} = \tilde{\epsilon} \epsilon = \epsilon_0^2 + \epsilon_1^2 + \epsilon_2^2 + \epsilon_3^2.$$

A unit quaternion can then be defined such that $\epsilon \tilde{\epsilon} = 1$. Often, ϵ_0 is referred to as the scalar part of the quaternion, and $(\epsilon_1 \ \epsilon_2 \ \epsilon_3)^T$ is referred to as the vector part.

Unit quaternions are used to describe orientation, and the unit magnitude provides the auxiliary relationship to resolve the use of superabundant (four) coordinates. A vector is defined in quaternion notation as a quaternion with $\epsilon_0 = 0$. Thus, a vector $\mathbf{p} = (p_x \ p_y \ p_z)^T$ can be expressed as a quaternion $\mathbf{p} = p_x i + p_y j + p_z k$. For any unit quaternion ϵ , the operation $\epsilon \mathbf{p} \tilde{\epsilon}$ performs a rotation of the vector \mathbf{p} about the direction $(\epsilon_1 \ \epsilon_2 \ \epsilon_3)^T$. This is clearly seen by expanding the operation $\epsilon \mathbf{p} \tilde{\epsilon}$ and comparing the results with the equivalent rotation matrix listed in Table 2.1. Also, as shown in Table 2.3, unit quaternions are closely related to the angle-axis representation. ϵ_0 corresponds (but is not equal) to the angle of rotation, while ϵ_1 , ϵ_2 , and ϵ_3 define the axis of rotation.

For velocity analysis, the time derivative of the quaternion can be related to the angular velocity vector as

$$\begin{pmatrix} \dot{\epsilon}_0 \\ \dot{\epsilon}_1 \\ \dot{\epsilon}_2 \\ \dot{\epsilon}_3 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} -\epsilon_1 & -\epsilon_2 & -\epsilon_3 \\ \epsilon_0 & \epsilon_3 & -\epsilon_2 \\ -\epsilon_3 & \epsilon_0 & \epsilon_1 \\ \epsilon_2 & -\epsilon_1 & \epsilon_0 \end{pmatrix} \begin{pmatrix} \omega_x \\ \omega_y \\ \omega_z \end{pmatrix}, \quad (2.8)$$

where $(\omega_x, \omega_y, \omega_z)^T = {}^j\boldsymbol{\omega}_i$ is given in fixed frame j . Defining $\boldsymbol{\epsilon}_{1:3} = (\epsilon_1, \epsilon_2, \epsilon_3)^T$, it is straightforward to verify that

$$\begin{aligned} \dot{\epsilon}_0 &= -\frac{1}{2} {}^j\boldsymbol{\omega}_i^T \boldsymbol{\epsilon}_{1:3} \\ \dot{\boldsymbol{\epsilon}}_{1:3} &= \frac{1}{2} (\epsilon_0 {}^j\boldsymbol{\omega}_i - \boldsymbol{\epsilon}_{1:3} \times {}^j\boldsymbol{\omega}_i). \end{aligned}$$

In the case that the angular velocity is given in the moving coordinates, these rate equations take a similar form.

$$\begin{aligned} \dot{\epsilon}_0 &= -\frac{1}{2} {}^i\boldsymbol{\omega}_i^T \boldsymbol{\epsilon}_{1:3} \\ \dot{\boldsymbol{\epsilon}}_{1:3} &= \frac{1}{2} (\epsilon_0 {}^i\boldsymbol{\omega}_i + \boldsymbol{\epsilon}_{1:3} \times {}^i\boldsymbol{\omega}_i) \end{aligned}$$

The corresponding rate matrix for this case is the same as (2.8) with the exception that the off-diagonal elements in the bottom 3×3 submatrix have opposite sign.

While a unit quaternion represents only the orientation of a body, quaternions may be dualized [2.5–7] to create an algebra that provides a description of the position and orientation of a body in space. Other combined representations are discussed in the following sections.

2.2.3 Homogeneous Transformations

The preceding sections have addressed representations of position and orientation separately. With homogeneous transformations, position vectors and rotation

matrices are combined together in a compact notation. Any vector ${}^i\mathbf{r}$ expressed relative to the i coordinate frame can be expressed relative to the j coordinate frame if the position and orientation of the i frame are known relative to the j frame. Using the notation of Sect. 2.2.1, the position of the origin of coordinate frame i relative to coordinate frame j can be denoted by the vector ${}^j\mathbf{p}_i = ({}^j p_i^x \ {}^j p_i^y \ {}^j p_i^z)^T$. Using the notation of Sect. 2.2.2, the orientation of frame i relative to frame j can be denoted by the rotation matrix ${}^j\mathbf{R}_i$. Thus,

$${}^j\mathbf{r} = {}^j\mathbf{R}_i {}^i\mathbf{r} + {}^j\mathbf{p}_i. \quad (2.9)$$

This equation can be written

$$\begin{pmatrix} {}^j\mathbf{r} \\ 1 \end{pmatrix} = \begin{pmatrix} {}^j\mathbf{R}_i & {}^j\mathbf{p}_i \\ \mathbf{0}^T & 1 \end{pmatrix} \begin{pmatrix} {}^i\mathbf{r} \\ 1 \end{pmatrix}, \quad (2.10)$$

where

$${}^j\mathbf{T}_i = \begin{pmatrix} {}^j\mathbf{R}_i & {}^j\mathbf{p}_i \\ \mathbf{0}^T & 1 \end{pmatrix} \quad (2.11)$$

is the 4×4 homogeneous transformation matrix and $({}^j\mathbf{r} \ 1)^T$ and $({}^i\mathbf{r} \ 1)^T$ are the homogeneous representations of the position vectors ${}^j\mathbf{r}$ and ${}^i\mathbf{r}$. The matrix ${}^j\mathbf{T}_i$ transforms vectors from coordinate frame i to coordinate frame j . Its inverse ${}^j\mathbf{T}_i^{-1}$ transforms vectors from coordinate frame j to coordinate frame i .

$${}^j\mathbf{T}_i^{-1} = {}^i\mathbf{T}_j = \begin{pmatrix} {}^j\mathbf{R}_i^T & -{}^j\mathbf{R}_i^T {}^j\mathbf{p}_i \\ \mathbf{0}^T & 1 \end{pmatrix}. \quad (2.12)$$

Composition of 4×4 homogeneous transformation matrices is accomplished through simple matrix multiplication, just as in the case of 3×3 rotation matrices. Therefore, ${}^k\mathbf{T}_i = {}^k\mathbf{T}_j {}^j\mathbf{T}_i$. Since matrix multiplications do not commute, the order or sequence is important.

The homogeneous transformation of a simple rotation about an axis is sometimes denoted **Rot** such that a rotation of θ about an axis $\hat{\mathbf{z}}$ is

$$\mathbf{Rot}(\hat{\mathbf{z}}, \theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 & 0 \\ \sin \theta & \cos \theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (2.13)$$

Similarly, the homogeneous transformation of a simple translation along an axis is sometimes denoted **Trans** such that a translation of d along an axis $\hat{\mathbf{x}}$ is

$$\mathbf{Trans}(\hat{\mathbf{x}}, d) = \begin{pmatrix} 1 & 0 & 0 & d \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (2.14)$$

Homogeneous transformations are particularly attractive when compact notation is desired and/or when ease of programming is the most important consideration. This is not, however, a computationally efficient representation since it introduces a large number of additional multiplications by ones and zeros. Although homogeneous transformation matrices technically contain 16 elements, four are defined to be zero or one, and the remaining elements are composed of a rotation matrix and a position vector. Therefore, the only truly superabundant coordinates come from the rotation matrix component, so the relevant auxiliary relationships are those associated with the rotation matrix.

2.2.4 Screw Transformations

The transformation in (2.9) can be viewed as composed of a rotation between coordinate frames i and j and a separate displacement between those frames. To get from frame i to frame j , one could perform the rotation first, followed by the displacement, or vice versa. Alternatively, the spatial displacement between the frames can be expressed, except in the case of a pure translation, as a rotation about a unique line combined with a translation parallel to that line.

Chasles' Theorem

Chasles' theorem, in the form stated by Chirikjian and Kyatkin [2.8], has two parts. The first states that:

Any displacement of a body in space can be accomplished by means of a translation of a designated point from its initial to its final position, followed by a rotation of the whole body about that point to bring it into its final orientation.

The second part states that:

Any displacement of a body in space can be accomplished by means of a rotation of the body about a unique line in space accompanied by a translation of the body parallel to that line.

Such a line is called a screw axis, and it is this second result that is usually thought of as Chasles' theorem.

The first part of the theorem is almost axiomatic. A designated point in a body anywhere in Euclidean space can be displaced from a given initial position to a given final position. By further requiring that all points in the body traverse the same displacement, the body translates so that the designated point moves from its initial position to its final position. The body can then be rotated about that point into any given final orientation.

The second part of the theorem depends on this representation of a spatial displacement and requires

a more complex argument. A preliminary theorem due to Euler allows greater specificity about the rotation of the body: *Any displacement of a body in which one point remains fixed is equivalent to a rotation of that body about a unique axis passing through that point.* Geometrically, embedding three points in the moving body and letting one be the fixed point about which rotation occurs, each of the other two will have initial and final positions. The right bisector planes of the lines joining the initial and final positions in each case necessarily contain the fixed point. Any line in the bisector plane can be the axis of a rotation that carries the corresponding point from its initial to its final position. Therefore, the unique line common to the two bisector planes is such that rotation about it will carry any point in the body from its initial to its final position. The rigidity condition requires that all planes in the body that contain that line rotate through the same angle.

For any rotation of a rigid body described by a rotation matrix ${}^j\mathbf{R}_i$, Euler's theorem states that there is a unique eigenvector $\hat{\mathbf{w}}$ such that

$${}^j\mathbf{R}_i\hat{\mathbf{w}} = \hat{\mathbf{w}}, \quad (2.15)$$

where $\hat{\mathbf{w}}$ is a unit vector parallel to the axis of rotation. This expression requires a unit eigenvalue of ${}^j\mathbf{R}_i$ corresponding to the eigenvector $\hat{\mathbf{w}}$. The remaining two eigenvalues are $\cos\theta \pm i\sin\theta$, where i is the complex operator and θ is the angle of rotation of the body about the axis.

Combining the first part of Chasles' theorem with Euler's theorem, a general spatial displacement can be expressed as a translation taking a point from its initial to its final position, followed by a unique rotation about a unique axis through that point that carries the body from its initial to its final orientation. Resolving the translation into components in the direction of and orthogonal to the rotation axis, every point in the body has the same displacement component in the direction of the axis because rotation about it does not affect that component. Projected onto a plane normal to the rotation axis, the kinematic geometry of the displacement is identical to that of planar motion. Just as there is a unique point in the plane about which a body could be rotated between two given positions, there is a unique point in the projection plane. If the rotation axis is moved to pass through that point, the spatial displacement can be accomplished by a rotation about that axis combined with a translation along it, as stated by the theorem.

The line about which rotation takes place is called the screw axis of the displacement. The ratio of the linear displacement d to the rotation θ is referred to as the

pitch h of the screw axis [2.4]. Thus,

$$d = h\theta. \quad (2.16)$$

The screw axis of a pure translation is not unique. Any line parallel to the translation can be regarded as the screw axis, and since the rotation θ is zero, the axis of a translation is said to have infinite pitch.

A screw axis is most conveniently represented in any coordinate frame by means of a unit vector $\hat{\mathbf{w}}$ parallel to it and the position vector $\boldsymbol{\rho}$ of any point lying on it. Additional specification of the pitch h and the angle of rotation θ completely defines the location of a second coordinate frame relative to the first frame. Thus, a total of eight coordinates define a screw transformation, which is superabundant by two. The unit magnitude of vector $\hat{\mathbf{w}}$ provides one auxiliary relationship, but in general, there is no second auxiliary relationship because the same screw axis is defined by all points lying on it, which is to say that the vector $\boldsymbol{\rho}$ contains one free coordinate.

Algebraically, a screw displacement is represented by

$${}^j\mathbf{r} = {}^j\mathbf{R}_i({}^i\mathbf{r} - \boldsymbol{\rho}) + d\hat{\mathbf{w}} + \boldsymbol{\rho}. \quad (2.17)$$

Comparing this expression to (2.9) yields

$${}^j\mathbf{p}_i = d\hat{\mathbf{w}} + (\mathbf{1}_{3 \times 3} - {}^j\mathbf{R}_i)\boldsymbol{\rho}. \quad (2.18)$$

$\mathbf{1}_{3 \times 3}$ denotes the 3×3 identity matrix. An expression for d is easily obtained by taking the inner product of both sides of the equation with $\hat{\mathbf{w}}$.

$$d = \hat{\mathbf{w}}^T {}^j\mathbf{p}_i. \quad (2.19)$$

The matrix $\mathbf{1}_{3 \times 3} - {}^j\mathbf{R}_i$ is singular, so (2.18) cannot be solved to give a unique value of $\boldsymbol{\rho}$, but since $\boldsymbol{\rho}$ can represent any point on the screw axis, this would not be appropriate. One component of $\boldsymbol{\rho}$ can be arbitrarily chosen, and any two of the component equations can then be solved to find the two other components of $\boldsymbol{\rho}$. All other points on the screw axis are then given by $\boldsymbol{\rho} + k\hat{\mathbf{w}}$, where k can take any value.

Table 2.4 contains the conversions between screw transformations and homogeneous transformations. Note that the equivalent rotation matrix for a screw transformation has the same form as the equivalent rotation matrix for an angle-axis representation of orientation in Table 2.1. Also, the auxiliary relationship that the vector $\boldsymbol{\rho}$ be orthogonal to the screw axis ($\hat{\mathbf{w}}^T \boldsymbol{\rho} = 0$) is used in Table 2.4 to provide a unique conversion to the screw transformation. The inverse result, that of finding the rotation matrix ${}^j\mathbf{R}_i$ and the translation ${}^j\mathbf{p}_i$ corresponding to a given screw displacement, is found from Rodrigues' equation.

Rodrigues' Equation

Given a screw axis, the angular displacement of a body about it, and the translation of the body along it, the displacement of an arbitrary point in that body can be found. Viewing a matrix transformation as describing the displacement of the body, this is equivalent to finding the matrix transformation equivalent to a given screw displacement.

Referring to Fig. 2.1, the position vectors of a point before and after a screw displacement can be geometrically related as

$$\begin{aligned} {}^j\mathbf{r} = & {}^i\mathbf{r} + d\hat{\mathbf{w}} + \sin \theta \hat{\mathbf{w}} \times ({}^i\mathbf{r} - \boldsymbol{\rho}) \\ & - (1 - \cos \theta)({}^i\mathbf{r} - \boldsymbol{\rho}) - ({}^i\mathbf{r} - \boldsymbol{\rho}) \cdot \hat{\mathbf{w}} \hat{\mathbf{w}}, \end{aligned} \quad (2.20)$$

where ${}^i\mathbf{r}$ and ${}^j\mathbf{r}$ denote the initial and final positions of the point, $\hat{\mathbf{w}}$ and $\boldsymbol{\rho}$ specify the screw axis, and θ and d give the displacement about it. This result is usually referred to as Rodrigues' equation [2.9], which can be written as a matrix transformation [2.10],

$${}^j\mathbf{r} = {}^j\mathbf{R}_i {}^i\mathbf{r} + {}^j\mathbf{p}_i, \quad (2.21)$$

since, when expanded, it gives three linear equations for the components of ${}^j\mathbf{r}$ in terms of those of ${}^i\mathbf{r}$.

$$\begin{aligned} {}^j\mathbf{R}_i = & \begin{pmatrix} w_x^2 v_\theta + c_\theta & w_x w_y v_\theta - w_z s_\theta & w_x w_z v_\theta + w_y s_\theta \\ w_x w_y v_\theta + w_z s_\theta & w_y^2 v_\theta + c_\theta & w_y w_z v_\theta - w_x s_\theta \\ w_x w_z v_\theta - w_y s_\theta & w_y w_z v_\theta + w_x s_\theta & w_z^2 v_\theta + c_\theta \end{pmatrix} \\ {}^j\mathbf{p}_i = & (\mathbf{1}_{3 \times 3} - {}^j\mathbf{R}_i)\boldsymbol{\rho} + h\theta \hat{\mathbf{w}}, \end{aligned}$$

Fig. 2.1 Initial and final positions of an arbitrary point in a body undergoing a screw displacement; ${}^i\mathbf{r}$ is the position of the point relative to the moving frame, which is coincident with the fixed frame j in its initial position; ${}^j\mathbf{r}$ is the position of the point relative to the fixed frame after the screw displacement of the moving body

Table 2.4 Conversions from a screw transformation to a homogeneous transformation and vice versa, with abbreviations $c_\theta := \cos \theta$, $s_\theta := \sin \theta$, and $v_\theta := 1 - \cos \theta$

Screw transformation to homogeneous transformation	${}^j\mathbf{R}_i = \begin{pmatrix} w_x^2 v_\theta + c_\theta & w_x w_y v_\theta - w_z s_\theta & w_x w_z v_\theta + w_y s_\theta \\ w_x w_y v_\theta + w_z s_\theta & w_y^2 v_\theta + c_\theta & w_y w_z v_\theta - w_x s_\theta \\ w_x w_z v_\theta - w_y s_\theta & w_y w_z v_\theta + w_x s_\theta & w_z^2 v_\theta + c_\theta \end{pmatrix}$ ${}^j\mathbf{p}_i = (\mathbf{1}_{3 \times 3} - {}^j\mathbf{R}_i)\boldsymbol{\rho} + h\theta \hat{\mathbf{w}}$
Homogeneous transformation to screw transformation	$\mathbf{l} = \begin{pmatrix} r_{32} - r_{23} \\ r_{13} - r_{31} \\ r_{21} - r_{12} \end{pmatrix}^T$ $\theta = \text{sign}(\mathbf{l}^T \mathbf{j}\mathbf{p}_i) \left \cos^{-1} \left(\frac{r_{11} + r_{22} + r_{33} - 1}{2} \right) \right $ $h = \frac{\mathbf{l}^T \mathbf{j}\mathbf{p}_i}{2\theta \sin \theta}$ $\boldsymbol{\rho} = \frac{(\mathbf{1}_{3 \times 3} - {}^j\mathbf{R}_i^T) \mathbf{j}\mathbf{p}_i}{2(1 - \cos \theta)}$ $\hat{\mathbf{w}} = \frac{\mathbf{l}}{2 \sin \theta}$

where the abbreviations are $c_\theta := \cos \theta$, $s_\theta := \sin \theta$, and $v_\theta = 1 - \cos \theta$. The rotation matrix ${}^j\mathbf{R}_i$ expressed in this form is also called the screw matrix, and these equations give the elements of ${}^j\mathbf{R}_i$ and ${}^j\mathbf{p}_i$ in terms of the screw parameters.

An exception arises in the case of a pure translation, for which $\theta = 0$ and Rodrigues' equation becomes

$${}^j\mathbf{r} = {}^i\mathbf{r} + d\hat{\mathbf{w}}. \quad (2.22)$$

Substituting for this case, ${}^j\mathbf{R}_i = \mathbf{1}_{3 \times 3}$ and ${}^j\mathbf{p}_i = d\hat{\mathbf{w}}$.

Additional information on screw theory can be found in [2.11–15].

2.2.5 Matrix Exponential Parameterization

The position and orientation of a body can also be expressed in a unified fashion with an exponential mapping. This approach is introduced first with its application to pure rotation and expanded to rigid-body motion. More details on the approach can be found in [2.16] and [2.17].

Exponential Coordinates for Rotation

The set of all orthogonal matrices with determinant 1, which is the set of all rotation matrices \mathbf{R} , is a *group* under the operation of matrix multiplication denoted as $SO(3) \subset \mathbb{R}^{3 \times 3}$ [2.18]. This stands for *special orthogonal* wherein *special* alludes to the $\det \mathbf{R}$ being +1 instead of ± 1 . The set of rotation matrices satisfies the four axioms of a group:

- **Closure:** $\mathbf{R}_1 \mathbf{R}_2 \in SO(3) \quad \forall \mathbf{R}_1, \mathbf{R}_2 \in SO(3)$
- **Identity:** $\mathbf{1}_{3 \times 3} \mathbf{R} = \mathbf{R} \mathbf{1}_{3 \times 3} = \mathbf{R} \quad \forall \mathbf{R} \in SO(3)$
- **Inverse:** $\mathbf{R}^T \in SO(3)$ is the unique inverse of $\mathbf{R} \quad \forall \mathbf{R} \in SO(3)$

- **Associativity:** $(\mathbf{R}_1 \mathbf{R}_2) \mathbf{R}_3 = \mathbf{R}_1 (\mathbf{R}_2 \mathbf{R}_3) \quad \forall \mathbf{R}_1, \mathbf{R}_2, \mathbf{R}_3 \in SO(3)$.

In the angle-axis representation presented in Sect. 2.2.2, orientation is expressed as an angle θ of rotation about an axis defined by the unit vector $\hat{\mathbf{w}}$. The equivalent rotation matrix found in Table 2.1 can be expressed as the exponential map

$$\begin{aligned} \mathbf{R} &= e^{\mathbf{S}(\hat{\mathbf{w}})\theta} \\ &= \mathbf{1}_{3 \times 3} + \theta \mathbf{S}(\hat{\mathbf{w}}) + \frac{\theta^2}{2!} \mathbf{S}(\hat{\mathbf{w}})^2 \\ &\quad + \frac{\theta^3}{3!} \mathbf{S}(\hat{\mathbf{w}})^3 + \dots, \end{aligned} \quad (2.23)$$

where $\mathbf{S}(\hat{\mathbf{w}})$ is the unit skew-symmetric matrix

$$\mathbf{S}(\hat{\mathbf{w}}) = \begin{pmatrix} 0 & -w_z & w_y \\ w_z & 0 & -w_x \\ -w_y & w_x & 0 \end{pmatrix}. \quad (2.24)$$

Thus, the exponential map transforms a skew-symmetric matrix $\mathbf{S}(\hat{\mathbf{w}})$ that corresponds to an axis of rotation $\hat{\mathbf{w}}$ into an orthogonal matrix \mathbf{R} that corresponds to a rotation about the axis $\hat{\mathbf{w}}$ through an angle of θ . It can be shown that the closed-form expression for $e^{\mathbf{S}(\hat{\mathbf{w}})\theta}$, which can be efficiently computed, is

$$e^{\mathbf{S}(\hat{\mathbf{w}})\theta} = \mathbf{1}_{3 \times 3} + \mathbf{S}(\hat{\mathbf{w}}) \sin \theta + \mathbf{S}(\hat{\mathbf{w}})^2 (1 - \cos \theta). \quad (2.25)$$

The components of $(\theta w_x \theta w_y \theta w_z)^T$, which are related to the elements of the rotation matrix \mathbf{R} in Table 2.2, are referred to as the *exponential coordinates* for \mathbf{R} .

Exponential Coordinates for Rigid-Body Motion

As indicated in Sect. 2.2.3, the position and orientation of a body can be expressed by the combination of a position vector $\mathbf{p} \in \mathbb{R}^3$ and a rotation matrix $\mathbf{R} \in SO(3)$. The product space of \mathbb{R}^3 with $SO(3)$ is the group known as $SE(3)$, which stands for *special Euclidean*.

$$\begin{aligned} SE(3) &= \{(\mathbf{p}, \mathbf{R}) : \mathbf{p} \in \mathbb{R}^3, \mathbf{R} \in SO(3)\} \\ &= \mathbb{R}^3 \times SO(3). \end{aligned}$$

The set of homogeneous transformations satisfies the four axioms of a group:

- *Closure*: $\mathbf{T}_1 \mathbf{T}_2 \in SE(3) \quad \forall \mathbf{T}_1, \mathbf{T}_2 \in SE(3)$
- *Identity*: $\mathbf{1}_{4 \times 4} \mathbf{T} = \mathbf{T} \mathbf{1}_{4 \times 4} = \mathbf{T} \quad \forall \mathbf{T} \in SE(3)$
- *Inverse*: the unique inverse of $\mathbf{T} \in SE(3)$ is given in (2.12)
- *Associativity*: $(\mathbf{T}_1 \mathbf{T}_2) \mathbf{T}_3 = \mathbf{T}_1 (\mathbf{T}_2 \mathbf{T}_3) \quad \forall \mathbf{T}_1, \mathbf{T}_2, \mathbf{T}_3 \in SE(3)$.

In the screw transformation representation in Sect. 2.2.4, position and orientation are expressed by the angle θ of rotation about a screw axis defined by the unit vector $\hat{\mathbf{w}}$, the point $\boldsymbol{\rho}$ on the axis such that $\hat{\mathbf{w}}^T \boldsymbol{\rho} = 0$, and the pitch h of the screw axis. The equivalent homogeneous transformation found in Table 2.4 can be expressed as the exponential map

$$\mathbf{T} = e^{\hat{\boldsymbol{\xi}}\theta} = \mathbf{1}_{4 \times 4} + \hat{\boldsymbol{\xi}}\theta + \frac{(\hat{\boldsymbol{\xi}}\theta)^2}{2!} + \frac{(\hat{\boldsymbol{\xi}}\theta)^3}{3!} + \dots, \quad (2.26)$$

where

$$\hat{\boldsymbol{\xi}} = \begin{pmatrix} S(\hat{\mathbf{w}}) & \mathbf{v} \\ \mathbf{0}^T & 0 \end{pmatrix} \quad (2.27)$$

is the generalization of the unit skew-symmetric matrix $\mathbf{S}(\hat{\mathbf{w}})$ known as a *twist*. The twist coordinates of $\hat{\boldsymbol{\xi}}$ are given by $\boldsymbol{\xi} := (\hat{\mathbf{w}}^T \mathbf{v})^T$. It can be shown that the closed-form expression for $e^{\hat{\boldsymbol{\xi}}\theta}$ is

$$\begin{aligned} e^{\hat{\boldsymbol{\xi}}\theta} &= \\ &\begin{pmatrix} e^{S(\hat{\mathbf{w}})\theta} & (\mathbf{1}_{3 \times 3} - e^{S(\hat{\mathbf{w}})\theta})(\hat{\mathbf{w}} \times \mathbf{v}) + \hat{\mathbf{w}}^T \mathbf{v} \theta \hat{\mathbf{w}} \\ \mathbf{0}^T & 1 \end{pmatrix}. \end{aligned} \quad (2.28)$$

Comparison of this result with the conversion between homogeneous and screw transformations in Table 2.4 yields

$$\mathbf{v} = \boldsymbol{\rho} \times \hat{\mathbf{w}} \quad (2.29)$$

and

$$h = \hat{\mathbf{w}}^T \mathbf{v}. \quad (2.30)$$

Thus, the exponential map for a twist transforms the initial pose of a body into its final pose. It gives the relative rigid-body motion. The vector $\boldsymbol{\xi}\theta$ contains the *exponential coordinates* for the rigid-body transformation.

As for screw transformations, the case of pure translation is unique. In this case, $\hat{\mathbf{w}} = \mathbf{0}$, so

$$e^{\hat{\boldsymbol{\xi}}\theta} = \begin{pmatrix} \mathbf{1}_{3 \times 3} & \theta \mathbf{v} \\ \mathbf{0}^T & 1 \end{pmatrix}. \quad (2.31)$$

2.2.6 Plücker Coordinates

A minimum of four coordinates are needed to define a line in space. The Plücker coordinates of a line form a six-dimensional (6-D) vector, so they are superabundant by two. They can be viewed as a pair of three-dimensional (3-D) vectors; one is parallel to the line, and the other is the *moment* of that vector about the origin. Thus, if \mathbf{u} is any vector parallel to the line and $\boldsymbol{\rho}$ is the position of any point on the line relative to the origin, the Plücker coordinates (L, M, N, P, Q, R) are given by

$$(L, M, N) = \mathbf{u}^T; \quad (P, Q, R) = (\boldsymbol{\rho} \times \mathbf{u})^T. \quad (2.32)$$

For simply defining a line, the magnitude of \mathbf{u} is not unique, nor is the component of $\boldsymbol{\rho}$ parallel to \mathbf{u} . Two auxiliary relationships are imposed to reduce the set to just four independent coordinates. One is that the scalar product of the two three-dimensional vectors is identically zero.

$$LP + MQ + NR \equiv 0. \quad (2.33)$$

The other is the invariance of the line designated when the coordinates are all multiplied by the same scaling factor.

$$(L, M, N, P, Q, R) \equiv (kL, kM, kN, kP, kQ, kR). \quad (2.34)$$

This relationship may take the form of constraining \mathbf{u} to have unit magnitude so that L, M , and N are the direction cosines.

In this handbook, it is often useful to express velocities in Plücker coordinates, wherein unlike the definition of lines, the magnitudes of the two three-dimensional vectors are not arbitrary. This leads to the motor notation of *von Mises* [2.9, 19] and *Everett* [2.20]. For instantaneously coincident coordinate frames, one fixed and the other embedded in the moving body, $\boldsymbol{\omega}$ is the angular velocity of the body and \mathbf{v}_O is the velocity of the origin O of the body-fixed frame when both are expressed relative to the fixed frame. This provides a Plücker coordinate system for the spatial velocity \mathbf{v} of the body. The Plücker coordinates of \mathbf{v}

are simply the Cartesian coordinates of $\boldsymbol{\omega}$ and \mathbf{v}_O ,

$$\mathbf{v} = \begin{pmatrix} \boldsymbol{\omega} \\ \mathbf{v}_O \end{pmatrix}. \quad (2.35)$$

The transformation from Plücker coordinate system i to Plücker coordinate system j for spatial velocities is achieved with the spatial transform ${}^j\mathbf{X}_i$. If \mathbf{v}_i and \mathbf{v}_j denote the spatial velocities of a body relative to the i and j frames, respectively, and ${}^j\mathbf{p}_i$ and ${}^j\mathbf{R}_i$ denote the position and orientation of frame i relative to frame j ,

$$\mathbf{v}_j = {}^j\mathbf{X}_i \mathbf{v}_i, \quad (2.36)$$

where

$${}^j\mathbf{X}_i = \begin{pmatrix} {}^j\mathbf{R}_i & \mathbf{0}_{3 \times 3} \\ \mathbf{S}({}^j\mathbf{p}_i){}^j\mathbf{R}_i & {}^j\mathbf{R}_i \end{pmatrix}, \quad (2.37)$$

such that

$${}^j\mathbf{X}_i^{-1} = {}^i\mathbf{X}_j = \begin{pmatrix} {}^i\mathbf{R}_j & \mathbf{0}_{3 \times 3} \\ -{}^i\mathbf{R}_j \mathbf{S}({}^j\mathbf{p}_i) & {}^i\mathbf{R}_j \end{pmatrix}, \quad (2.38)$$

and

$${}^k\mathbf{X}_i = {}^k\mathbf{X}_j {}^j\mathbf{X}_i, \quad (2.39)$$

and $\mathbf{S}({}^j\mathbf{p}_i)$ is the skew-symmetric matrix

$$\begin{pmatrix} 0 & -{}^j p_i^z & {}^j p_i^y \\ {}^j p_i^z & 0 & -{}^j p_i^x \\ -{}^j p_i^y & {}^j p_i^x & 0 \end{pmatrix}. \quad (2.40)$$

Spatial vector notation, which includes the spatial velocities and transforms briefly mentioned here, is treated in greater depth in Sect. 3.2. Specifically, Table 3.1 gives a computationally efficient algorithm for applying a spatial transform.

2.3 Joint Kinematics

Unless explicitly stated otherwise, the kinematic description of robotic mechanisms typically employs a number of idealizations. The links that compose the robotic mechanism are assumed to be perfectly rigid bodies having surfaces that are geometrically perfect in both position and shape. Accordingly, these rigid bodies are connected together at joints where their idealized surfaces are in ideal contact without any clearance between them. The respective geometries of these surfaces in contact determine the freedom of motion between the two links, or the *joint kinematics*.

A kinematic joint is a connection between two bodies that constrains their relative motion. Two bodies that are in contact with one another create a simple kinematic joint. The surfaces of the two bodies that are in contact are able to move over one another, thereby permitting relative motion of the two bodies. Simple kinematic joints are classified as lower pair joints if contact occurs over surfaces [2.21] and as higher pair joints if contact occurs only at points or along lines.

A joint model describes the motion of a frame fixed in one body of a joint relative to a frame fixed in the other body. The motion is expressed as a function of the joint's motion variables, and other elements of a joint model include the rotation matrix, position vector, free modes, and constrained modes. The free modes of a joint define the directions in which motion is allowed. They are represented by the $6 \times n_i$ matrix Φ_i whose columns are the Plücker coordinates of the allowable

motion. This matrix relates the spatial velocity vector across the joint $\mathbf{v}_{\text{rel},i}$ to the joint velocity vector $\dot{\mathbf{q}}_i$,

$$\mathbf{v}_{\text{rel},i} = \Phi_i \dot{\mathbf{q}}_i. \quad (2.41)$$

In contrast, the constrained modes of a joint define the directions in which motion is not allowed. They are represented by the $6 \times (6 - n_i)$ matrix Φ_i^c that is complementary to Φ_i . Tables 2.5 and 2.6 contain the formulas of the joint models for all of the joints described in this section. They are used extensively for the dynamic analysis presented in Chap. 3. Additional information on joints can be found in Chap. 4.

2.3.1 Lower Pair Joints

Lower pair joints are mechanically attractive since wear is spread over the whole surface and lubricant is trapped in the small clearance space (in nonidealized systems) between the surfaces, resulting in relatively good lubrication. As can be proved [2.23] from the requirement for surface contact, there are only six possible forms of lower pair joints: revolute, prismatic, helical, cylindrical, spherical, and planar joints.

Revolute

The most general form of a revolute joint, often abbreviated as R and sometimes referred to colloquially as a hinge or pin joint, is a lower pair composed of two

Table 2.5 Joint model formulas for one-degree-of-freedom lower pair joints, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$ (adapted in part from Table 4.1 in [2.22])

Joint type	Joint rotation matrix iR_i	Position vector ${}^i p_i$	Free modes Φ_i	Constrained modes Φ_i^c	Pose state vars.	\dot{q}_i
Revolute R	$\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$	θ_i	$\dot{\theta}_i$
Prismatic P	$\mathbf{1}_{3 \times 3}$	$\begin{pmatrix} 0 \\ 0 \\ d_i \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}$	d_i	\dot{d}_i
Helical H (pitch h)	$\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ h\theta_i \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ h \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -h \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$	θ_i	$\dot{\theta}_i$

congruent surfaces of revolution. The surfaces are the same except one of them is an external surface, convex in any plane normal to the axis of revolution, and one is an internal surface, concave in any plane normal to the axis. The surfaces may not be solely in the form of right circular cylinders, since surfaces of that form do not provide any constraint on axial sliding. A revolute joint permits only rotation of one of the bodies joined relative to the other. The position of one body relative to the other may be expressed as the angle between two lines normal to the joint axis, one fixed in each body. Thus, the joint has one *degree of freedom* (DOF). When the \hat{z} axis of coordinate frame i is aligned with a revolute joint axis, the formulas in Table 2.5 define the revolute joint model.

Prismatic

The most general form of a prismatic joint, often abbreviated as **P** and sometimes referred to colloquially as a sliding joint, is a lower pair formed from two congruent general cylindrical surfaces. These may not be right circular cylindrical surfaces. A general cylindrical surface is obtained by extruding any curve in a constant direction. Again, one surface is internal and the other is an external surface. A prismatic joint permits only sliding of one of the members joined relative to the other along the direction of extrusion. The position of one body relative to the other is determined by the distance between two points on a line parallel to the direction of sliding, with one point fixed in each body. Thus, this joint also has one degree of freedom. When the \hat{z} axis

of coordinate frame i is aligned with a prismatic joint axis, the formulas in Table 2.5 define the prismatic joint model.

Helical

The most general form of a helical joint, often abbreviated as **H** and sometimes referred to colloquially as a screw joint, is a lower pair formed from two helicoidal surfaces formed by extruding any curve along a helical path. The simple example is a bolt and nut wherein the basic generating curve is a pair of straight lines. The angle θ of rotation about the axis of the helical joint is directly related to the distance d of displacement of one body relative to the other along that axis by the expression $d = h\theta$, where the constant h is called the pitch of the helical joint. When the \hat{z} axis of coordinate frame i is aligned with a helical joint axis, the formulas in Table 2.5 define the helical joint model.

Cylindrical

A cylindrical joint, often abbreviated as **C**, is a lower pair formed by contact of two congruent right circular cylinders, one an internal surface and the other an external surface. It permits both rotation about the cylinder axis and sliding parallel to it. Therefore, it is a joint with two degrees of freedom. Lower pair joints with more than one degree of freedom are easily replaced by kinematically equivalent compound joints (Sect. 2.3.3) that are serial chains of one-degree-of-freedom lower pairs. In the present case, the cylindrical joint can be replaced by a revolute in series with a pris-

Table 2.6 Joint model formulas for higher-degree-of-freedom lower pair joints, universal joint, rolling contact joint, and 6-DOF joint, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$ (adapted in part from Table 4.1 in [2.22]) *The Euler angles α_i , β_i , and γ_i could be used in place of the unit quaternion ϵ_i to represent orientation

Joint type	Joint rotation matrix ${}^J R_i$	Position vector ${}^J p_i$	Free modes Φ_i	Constrained modes Φ_i^c	Pose Variables	Velocity Variables \dot{q}_i

Univer- sal U	$\begin{pmatrix} c_{\alpha_i} c_{\beta_i} & -s_{\alpha_i} & c_{\alpha_i} s_{\beta_i} \\ s_{\alpha_i} c_{\beta_i} & c_{\alpha_i} & s_{\alpha_i} s_{\beta_i} \\ -s_{\beta_i} & 0 & c_{\beta_i} \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$	$\begin{pmatrix} -s_{\beta_i} & 0 \\ 0 & 1 \\ c_{\beta_i} & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}$	$\begin{pmatrix} c_{\beta_i} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ s_{\beta_i} & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	α_i β_i	$\begin{pmatrix} \dot{\alpha}_i \\ \dot{\beta}_i \end{pmatrix}$
6-DOF*	$\begin{pmatrix} \text{see} \\ \text{Table 2.1} \end{pmatrix}$	${}^0 p_i$	$\mathbf{1}_{6 \times 6}$		ϵ_i ${}^0 p_i$	$\begin{pmatrix} \omega_i \\ v_i \end{pmatrix}$

matic joint whose direction of sliding is parallel to the revolute axis. While simpler to implement using the geometric representation discussed in Sect. 2.4, this approach has disadvantages for dynamic simulation. Modeling a single cylindrical joint as a combination of a prismatic and a revolute joint requires the addition of a virtual link between the two with zero mass and zero length. The massless link can create computational problems. When the \hat{z} axis of coordinate frame i is aligned with a cylindrical joint axis, the formulas in Table 2.6 define the cylindrical joint model.

Spherical

A spherical joint, often abbreviated as S , is a lower pair formed by contact of two congruent spherical surfaces. Once again, one is an internal surface, and the other is an external surface. A spherical joint permits rotation about any line through the center of the sphere. Thus, it permits independent rotation about axes in up to three different directions and has three degrees of freedom. A spherical joint is easily replaced by a kinematically equivalent compound joint consisting of three revolute joints that have axes that all intersect in a single point – the center of the spherical joint. The revolute joint axes

do not need to be successively orthogonal, but often they are implemented that way. The arrangement is, in general, kinematically equivalent to a spherical joint, but it does exhibit a singularity when the revolute joint axes become coplanar. This is as compared to the native spherical joint that never has such a singularity. Likewise, if a spherical joint is modeled in simulation as three revolutes, computational difficulties again can arise from the necessary inclusion of massless virtual links having zero length. The joint model formulas of a spherical joint are given in Table 2.6.

Planar

A planar joint is formed by planar contacting surfaces. Like the spherical joint, it is a lower pair joint with three degrees of freedom. A kinematically equivalent compound joint consisting of a serial chain of three revolutes with parallel axes can replace a planar joint. As was the case with the spherical joint, the compound joint exhibits a singularity when the revolute axes become coplanar. When the \hat{z} axis of coordinate frame i is aligned with the normal to the plane of contact, the formulas in Table 2.6 define the planar joint model.

2.3.2 Higher Pair Joints

Some higher pair joints also have attractive properties, particularly rolling pairs in which one body rolls without slipping over the surface of the other. This is mechanically attractive since the absence of sliding means the absence of abrasive wear. However, since ideal contact occurs at a point, or along a line, application of a load across the joint may lead to very high local stresses resulting in other forms of material failure and, hence, wear. Higher pair joints can be used to create kinematic joints with special geometric properties, as in the case of a gear pair or a cam and follower pair.

Rolling Contact

Rolling contact actually encompasses several different geometries. Rolling contact in planar motion permits one degree of freedom of relative motion as in the case of a roller bearing, for example. Planar rolling contact can take place along a line, thereby spreading the load and wear somewhat. Three-dimensional rolling contact allows rotation about any axis through the point of contact that is, in principle, unique. Hence, a three-dimensional rolling contact pair permits relative motion with three degrees of freedom. When the \hat{z} axis of coordinate frame i is aligned with the axis of rotation and passes through the center of the roller of fixed radius r , the formulas in Table 2.6 define the planar rolling contact joint model for a roller on a flat surface.

Regardless of whether the joint is planar or three-dimensional, the *no-slip* condition associated with a rolling contact joint requires that the instantaneous relative velocity between the points on the two bodies in contact be zero. If P is the point of rolling contact between bodies i and j ,

$$\mathbf{v}_{P_i/P_j} = 0. \quad (2.42)$$

Likewise, relative acceleration is in the direction of the common normal to the two surfaces at the point of contact. Because the constraint associated with the joint is expressed in terms of velocity and cannot be expressed in terms of position alone, it is nonholonomic, as discussed in Sect. 2.3.6. A more detailed discussion of the kinematic constraints for rolling contact is found in Chap. 24.

2.3.3 Compound Joints

Compound kinematic joints are connections between two bodies formed by chains of other members and simple kinematic joints. A compound joint may constrain the relative motion of the two bodies joined in the same way as a simple joint. In such a case, the two joints are said to be kinematically equivalent.

Universal

A universal joint, often abbreviated as *U* and referred to as a Cardan or Hooke joint, is a compound joint with two degrees of freedom. It consists of a serial chain of two revolutes whose axes intersect orthogonally. The joint model for a universal joint, in which, from Euler angle notation, α_i is the first rotation about the Z -axis and then β_i is the rotation about the Y -axis, is given in Table 2.6. This is a joint for which the matrices Φ_i and Φ_i^c are not constant, so in general, $\dot{\Phi}_i \neq 0$ and $\dot{\Phi}_i^c \neq 0$. As seen in Table 2.6, the orientation of the first joint axis (expressed in the outboard coordinate frame) varies with β_i .

2.3.4 6-DOF Joint

The motion of two bodies not jointed together can be modeled as a six-degree-of-freedom *joint* that introduces no constraints. This is particularly useful for mobile robots, such as aircraft, that make at most intermittent contact with the ground, and thus, a body in free motion relative to the fixed frame is termed a *floating base*. Such a free motion joint model enables the position and orientation of a floating base in space to be expressed with six joint variables. The 6-DOF joint model is included in Table 2.6.

2.3.5 Physical Realization

In an actual robotic mechanism, the joints may have physical limits beyond which motion is prohibited. The workspace (Sect. 2.5) of a robotic manipulator is determined by considering the combined limits and freedom of motion of all the joints within the mechanism. Revolute joints are easily actuated by rotating motors and are, therefore, extremely common in robotic systems. They may also be present as passive, unactuated joints. Also common, although less so than revolute, prismatic joints are relatively easily actuated by means of linear actuators such as hydraulic or pneumatic cylinders, ball screws, or screw jacks. They always have motion limits since unidirectional sliding can, in principle, produce infinite displacements. Helical joints are most often found in robotic mechanisms as constituents of linear actuators such as screw jacks and ball screws and are seldom used as primary kinematic joints. Joints with more than one degree of freedom are generally used passively in robotic mechanisms because each degree of freedom of an active joint must be separately actuated. Passive spherical joints are quite often found in robotic mechanisms, while passive planar joints are only occasionally found. The effect of an actuated spherical joint is achieved by employing the kinematically equivalent combination of three revolute and actuating each. Universal joints are used in robotic mechanisms in both active and passive forms.

Serial chains are commonly denoted by the abbreviations for the joints they contain in the order in which they appear in the chain. For example, an RPR chain contains three links, the first jointed to the base with a revolute and to the second with a prismatic, while the second and third are jointed together with another revolute. If all of the joints are identical, the notation consists of the number of joints preceding the joint abbreviation, such as 6R for a six-axis serial-chain manipulator containing only revolute joints.

Joints are realized with hardware that is more complex than the idealizations presented in Sects. 2.3.1 and 2.3.2. For example, a revolute joint may be achieved with a ball bearing composed of a set of

bearing balls trapped between two journals. The balls ideally roll without slipping on the journals, thereby taking advantage of the special properties of rolling contact joints. A prismatic joint may be realized by means of a roller-rail assembly.

2.3.6 Holonomic and Nonholonomic Constraints

With the exception of rolling contact, all of the constraints associated with the joints discussed in the preceding sections can be expressed mathematically by equations containing only the joint position variables. These are called holonomic constraints. The number of equations, and hence the number of constraints, is $6 - n$, where n is the number of degrees of freedom of the joint. The constraints are intrinsically part of the axial joint model.

A nonholonomic constraint is one that cannot be expressed in terms of the position variables alone, but includes the time derivative of one or more of those variables. These constraint equations cannot be integrated to obtain relationships solely between the joint variables. The most common example in robotic systems arises from the use of a wheel or roller that rolls without slipping on another member. Nonholonomic constraints, particularly as they apply to wheeled robots, are discussed in more detail in Chap. 24.

2.3.7 Generalized Coordinates

In a robotic mechanism consisting of N bodies, $6N$ coordinates are required to specify the position and orientation of all the bodies relative to a coordinate frame. Since some of those bodies are jointed together, a number of constraint equations will establish relationships among some of these coordinates. In this case, the $6N$ coordinates can be expressed as functions of a smaller set of coordinates \mathbf{q} that are all independent. The coordinates in this set are known as generalized coordinates, and motions associated with these coordinates are consistent with all of the constraints. The joint variables \mathbf{q} of a robotic mechanism form a set of generalized coordinates [2.24, 25].

2.4 Geometric Representation

The geometry of a robotic mechanism is conveniently defined by attaching coordinate frames to each link. While these frames could be located arbitrarily, it is advantageous both for consistency and computational efficiency to adhere to a convention for locating the frames on the links. Denavit and Hartenberg [2.26] introduced

the foundational convention that has been adapted in a number of different ways, one of which is the convention introduced by Khalil and Dombre [2.27] used throughout this handbook. In all of its forms, the convention requires only four rather than six parameters to locate one coordinate frame relative to another. The

four parameters consist of two link parameters, the link length a_i and the link twist α_i , and two joint parameters, the joint offset d_i and the joint angle θ_i . This parsimony is achieved through judicious placement of the coordinate frame origins and axes such that the \hat{x} axis of one frame both intersects and is perpendicular to the \hat{z} axis of the following coordinate frame. The convention is applicable to robotic mechanisms consisting of revolute and prismatic joints, so when multiple-degree-of-freedom joints are present, they are modeled as combinations of revolute and prismatic joints, as discussed in Sect. 2.3.

There are essentially four different forms of the convention for locating coordinate frames in a robotic mechanism. Each exhibits its own advantages by managing trade-offs of intuitive presentation. In the original Denavit and Hartenberg [2.26] convention, joint i is located between links i and $i + 1$, so it is on the outboard side of link i . Also, the joint offset d_i and joint angle θ_i are measured along and about the $i - 1$ joint axis, so the subscripts of the joint parameters do not match that of the joint axis. Waldron [2.28] and Paul [2.29] modified the labeling of axes in the original convention such that joint i is located between links $i - 1$ and i in order to make it consistent with the base member of a serial chain being member 0. This places joint i at the inboard side of link i and is the convention used in all of the other modified versions. Furthermore, Waldron and Paul addressed the mismatch between subscripts of the joint parameters and joint axes by placing the \hat{z}_i

axis along the $i + 1$ joint axis. This, of course, relocates the subscript mismatch to the correspondence between the joint axis and the \hat{z} axis of the coordinate frame. Craig [2.30] eliminated all of the subscript mismatches by placing the \hat{z}_i axis along joint i , but at the expense of the homogeneous transformation ${}^{i-1}\mathbf{T}_i$ being formed with a mixture of joint parameters with subscript i and link parameters with subscript $i - 1$. Khalil and Dombre [2.27] introduced another variation similar to Craig's except that it defines the link parameters a_i and α_i along and about the \hat{x}_{i-1} axis. In this case, the homogeneous transformation ${}^{i-1}\mathbf{T}_i$ is formed only by parameters with subscript i , and the subscript mismatch is such that a_i and α_i indicate the length and twist of link $i - 1$ rather than link i . Thus, in summary, the advantages of the convention used throughout this handbook compared to the alternative conventions are that the \hat{z} axes of the coordinate frames share the common subscript of the joint axes and the four parameters that define the spatial transform from coordinate frame i to coordinate frame $i - 1$ all share the common subscript i .

In this handbook, the convention for serial chain mechanisms is shown in Fig. 2.2 and summarized as follows. The numbering of bodies and joints follows the convention:

- The N moving bodies of the robotic mechanism are numbered from 1 to N . The number of the base is 0.
- The N joints of the robotic mechanism are numbered from 1 to N , with joint i located between members $i - 1$ and i .

Fig. 2.2 Schematic of the numbering of bodies and joints in a robotic mechanism, the convention for attaching coordinate frames to the bodies, and the definitions of the four parameters, a_i , α_i , d_i , and θ_i , that locate one frame relative to another

Fig. 2.3 Example six-degree-of-freedom serial chain manipulator composed of an articulated arm with no joint offsets and a spherical wrist

Table 2.7 Geometric parameters of the example serial chain manipulator in Fig. 2.3

i	α_i	a_i	d_i	θ_i
1	0	0	0	θ_1
2	$-\frac{\pi}{2}$	0	0	θ_2
3	0	a_3	0	θ_3
4	$-\frac{\pi}{2}$	0	d_4	θ_4
5	$\frac{\pi}{2}$	0	0	θ_5
6	$-\frac{\pi}{2}$	0	0	θ_6

With this numbering scheme, the attachment of coordinate frames follows the convention:

- The \hat{z}_i axis is located along the axis of joint i ,
- The \hat{x}_{i-1} axis is located along the common normal between the \hat{z}_{i-1} and \hat{z}_i axes.

Using the attached frames, the four parameters that locate one frame relative to another are defined as:

- a_i is the distance from \hat{z}_{i-1} to \hat{z}_i along \hat{x}_{i-1} ,
- α_i is the angle from \hat{z}_{i-1} to \hat{z}_i about \hat{x}_{i-1} ,
- d_i is the distance from \hat{x}_{i-1} to \hat{x}_i along \hat{z}_i ,
- θ_i is the angle from \hat{x}_{i-1} to \hat{x}_i about \hat{z}_i .

The geometric parameters for the example manipulator shown in Fig. 2.3 are listed in Table 2.7. All of the joints of this manipulator are revolute, and joint 1

has a vertical orientation. Joint 2 is perpendicular to joint 1 and intersects it. Joint 3 is parallel to joint 2, and the length of link 2 is a_3 . Joint 4 is perpendicular to joint 3 and intersects it. Joint 5 likewise intersects joint 4 perpendicularly at an offset of d_4 from joint 3. Finally, joint 6 intersects joint 5 perpendicularly.

With this convention, coordinate frame i can be located relative to coordinate frame $i-1$ by executing a rotation through an angle α_i about the \hat{x}_{i-1} axis, a translation of distance a_i along \hat{x}_{i-1} , a rotation through an angle θ_i about the \hat{z}_i axis, and a translation of distance d_i along \hat{z}_i . Through concatenation of these individual transformations,

$$\begin{aligned} & \mathbf{Rot}(\hat{x}_{i-1}, \alpha_i) \mathbf{Trans}(\hat{x}_{i-1}, a_i) \mathbf{Rot}(\hat{z}_i, \theta_i) \\ & \mathbf{Trans}(\hat{z}_i, d_i), \end{aligned} \quad (2.43)$$

the equivalent homogeneous transformation is,

$${}^{i-1}\mathbf{T}_i = \begin{pmatrix} \cos \theta_i & -\sin \theta_i & 0 & a_i \\ \sin \theta_i \cos \alpha_i & \cos \theta_i \cos \alpha_i & -\sin \alpha_i & -\sin \alpha_i d_i \\ \sin \theta_i \sin \alpha_i & \cos \theta_i \sin \alpha_i & \cos \alpha_i & \cos \alpha_i d_i \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (2.44)$$

The identification of geometric parameters is addressed in Chap. 8.

2.5 Workspace

Most generally, the workspace of a robotic manipulator is the total volume swept out by the end-effector as the manipulator executes all possible motions. The workspace is determined by the geometry of the manipulator and the limits of the joint motions. It is more specific to define the reachable workspace as the total locus of points at which the end-effector can be placed and the dextrous workspace [2.31] as the subset of those points at which the end-effector can be placed while having an arbitrary orientation. Dexterous workspaces exist only for certain idealized geometries, so real industrial manipulators with joint motion limits almost never possess dextrous workspaces.

Many serial-chain robotic manipulators are designed such that their joints can be partitioned into a regional structure and an orientation structure. The joints in the regional structure accomplish the positioning of the end-effector in space, and the joints in the orientation structure accomplish the orientation of the end-effector. Typically, the inboard joints of a se-

rial chain manipulator comprise the regional structure, while the outboard joints comprise the orientation structure. Also, since prismatic joints provide no capability for rotation, they are generally not employed within the orientation structure.

The regional workspace volume can be calculated from the known geometry of the serial-chain manipulator and motion limits of the joints. With three inboard joints comprising the regional structure, the area of workspace for the outer two (joints 2 and 3) is computed first, and then the volume is calculated by integrating over the joint variable of the remaining inboard joint (joint 1). In the case of a prismatic joint, this simply involves multiplying the area by the total length of travel of the prismatic joint. In the more common case of a revolute joint, it involves rotating the area about the joint axis through the full range of motion of the revolute [2.32]. By the theorem of Pappus, the associated volume V is

$$V = A\bar{r}\gamma, \quad (2.45)$$

where A is the area, \bar{r} is the distance from the area's centroid to the axis, and γ is the angle through which the area is rotated. The boundaries of the area are determined by tracing the motion of a reference point in the end-effector, typically the center of rotation of the wrist that serves as the orientation structure. Starting with each of the two joints at motion limits and with joint 2 locked, joint 3 is moved until its second motion limit is reached. Joint 3 is then locked, and joint 2

is freed to move to its second motion limit. Joint 2 is again locked, while joint 3 is freed to move back to its original motion limit. Finally, joint 3 is locked, and joint 2 freed to move likewise to its original motion limit. In this way, the trace of the reference point is a closed curve whose area and centroid can be calculated mathematically.

More details on manipulator workspace can be found in Chaps. 4 and 16.

2.6 Forward Kinematics

The forward kinematics problem for a serial-chain manipulator is to find the position and orientation of the end-effector relative to the base given the positions of all of the joints and the values of all of the geometric link parameters. Often, a frame fixed in the end-effector is referred to as the *tool frame*, and while fixed in the final link N , it in general has a constant offset in both position and orientation from frame N . Likewise, a *station frame* is often located in the base to establish the location of the task to be performed. This frame generally has a constant offset in its pose relative to frame 0, which is also fixed in the base.

A more general expression of the forward kinematics problem is to find the relative position and orientation of any two designated members given the geometric structure of the robotic mechanism and the values of a number of joint positions equal to the number of degrees of freedom of the mechanism. The forward kinematics problem is critical for developing manipulator coordination algorithms because joint positions are typically measured by sensors mounted on the joints and it is necessary to calculate the positions of the joint axes relative to the fixed frame.

In practice, the forward kinematics problem is solved by calculating the transformation between a coordinate frame fixed in the end-effector and another coordinate frame fixed in the base, i. e., between the tool and station frames. This is straightforward for a serial chain since the transformation describing the position of the end-effector relative to the base is obtained by simply concatenating transformations between frames fixed in adjacent links of the chain. The convention for the geometric representation of a manipulator presented in Sect. 2.4 reduces this to finding an equivalent 4×4 homogeneous transformation matrix that relates the spatial displacement of the end-effector coordinate frame to the base frame.

For the example serial-chain manipulator shown in Fig. 2.3 and neglecting the addition of tool and station

Table 2.8 Forward kinematics of the example serial chain manipulator in Fig. 2.3, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$

${}^0\mathbf{T}_6 = \begin{pmatrix} r_{11} & r_{12} & r_{13} & {}^0p_6^x \\ r_{21} & r_{22} & r_{23} & {}^0p_6^y \\ r_{31} & r_{32} & r_{33} & {}^0p_6^z \\ 0 & 0 & 0 & 1 \end{pmatrix},$
$r_{11} = c_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(s_{\theta_4}s_{\theta_6} - c_{\theta_4}c_{\theta_5}c_{\theta_6})$ $- c_{\theta_1}s_{\theta_5}c_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})$ $+ s_{\theta_1}(s_{\theta_4}c_{\theta_5}c_{\theta_6} + c_{\theta_4}s_{\theta_6}),$
$r_{21} = s_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(s_{\theta_4}s_{\theta_6} - c_{\theta_4}c_{\theta_5}c_{\theta_6})$ $- s_{\theta_1}s_{\theta_5}c_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})$ $- c_{\theta_1}(s_{\theta_4}c_{\theta_5}c_{\theta_6} + c_{\theta_4}s_{\theta_6}),$
$r_{31} = (c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})(s_{\theta_4}s_{\theta_6} - c_{\theta_4}c_{\theta_5}c_{\theta_6})$ $+ s_{\theta_5}c_{\theta_6}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}),$
$r_{12} = c_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(c_{\theta_4}c_{\theta_5}s_{\theta_6} + s_{\theta_4}c_{\theta_6})$ $+ c_{\theta_1}s_{\theta_5}s_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})$ $+ s_{\theta_1}(c_{\theta_4}c_{\theta_6} - s_{\theta_4}c_{\theta_5}s_{\theta_6}),$
$r_{22} = s_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(c_{\theta_4}c_{\theta_5}s_{\theta_6} + s_{\theta_4}c_{\theta_6})$ $+ s_{\theta_1}s_{\theta_5}s_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})$ $- c_{\theta_1}(c_{\theta_4}c_{\theta_6} - s_{\theta_4}c_{\theta_5}s_{\theta_6}),$
$r_{32} = (c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})(c_{\theta_4}c_{\theta_5}s_{\theta_6} + s_{\theta_4}c_{\theta_6})$ $- s_{\theta_5}s_{\theta_6}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}),$
$r_{13} = c_{\theta_1}c_{\theta_4}s_{\theta_5}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})$ $- c_{\theta_1}c_{\theta_5}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})$ $- s_{\theta_1}s_{\theta_4}s_{\theta_5},$
$r_{23} = s_{\theta_1}c_{\theta_4}s_{\theta_5}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})$ $- s_{\theta_1}c_{\theta_5}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) + c_{\theta_1}s_{\theta_4}s_{\theta_5},$
$r_{33} = c_{\theta_4}s_{\theta_5}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})$ $+ c_{\theta_5}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}),$
${}^0p_6^x = a_3c_{\theta_1}c_{\theta_2} - d_4c_{\theta_1}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}),$
${}^0p_6^y = a_3s_{\theta_1}c_{\theta_2} - d_4s_{\theta_1}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}),$
${}^0p_6^z = -a_3s_{\theta_2} + d_4(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}).$

frames, the transformation is

$${}^0\mathbf{T}_6 = {}^0\mathbf{T}_1 {}^1\mathbf{T}_2 {}^2\mathbf{T}_3 {}^3\mathbf{T}_4 {}^4\mathbf{T}_5 {}^5\mathbf{T}_6. \quad (2.46)$$

Table 2.8 contains the elements of ${}^0\mathbf{T}_6$ that are calculated using Table 2.7 and (2.44).

Once again, homogeneous transformations provide a compact notation, but are computationally inefficient for solving the forward kinematics problem. A reduction in computation can be achieved by separating the position and orientation portions of the transformation to eliminate all multiplications by the 0 and 1 elements of the matrices. In Chap. 3, calculations are made using the spatial vector notation briefly introduced here

2.7 Inverse Kinematics

The inverse kinematics problem for a serial-chain manipulator is to find the values of the joint positions given the position and orientation of the end-effector relative to the base and the values of all of the geometric link parameters. Once again, this is a simplified statement applying only to serial chains. A more general statement is: given the relative positions and orientations of two members of a mechanism, find the values of all of the joint positions. This amounts to finding all of the joint positions given the homogeneous transformation between the two members of interest.

In the common case of a six-degree-of-freedom serial chain manipulator, the known transformation is ${}^0\mathbf{T}_6$. Reviewing the formulation of this transformation in Sect. 2.6, it is clear that the inverse kinematics problem for serial-chain manipulators requires the solution of sets of nonlinear equations. In the case of a six-degree-of-freedom manipulator, three of these equations relate to the position vector within the homogeneous transformation, and the other three relate to the rotation matrix. In the latter case, these three equations cannot come from the same row or column because of the dependency within the rotation matrix. With these nonlinear equations, it is possible that no solutions exist or multiple solutions exist [2.33]. For a solution to exist, the desired position and orientation of the end-effector must lie in the workspace of the manipulator. In cases where solutions do exist, they often cannot be presented in closed form, so numerical methods are required.

2.7.1 Closed-Form Solutions

Closed-form solutions are desirable because they are faster than numerical solutions and readily identify all possible solutions. The disadvantage of closed-form so-

lutions is that they are not general, but robot dependent. The most effective methods for finding closed-form solutions are ad hoc techniques that take advantage of particular geometric features of specific mechanisms. In general, closed-form solutions can only be obtained for six-degree-of-freedom systems with special kinematic structure characterized by a large number of the geometric parameters defined in Sect. 2.4 being zero-valued. Most industrial manipulators have such structure because it permits more efficient coordination software. Sufficient conditions for a six-degree-of-freedom manipulator to have closed-form inverse kinematics solutions are [2.34–36]:

Kinematic trees are the general structure of robotic mechanisms that do not contain closed loops, and the forward kinematics of tree structures are addressed in Chap. 3. The forward kinematics problem for closed chains is much more complicated because of the additional constraints present. Solution methods for closed chains are included in Chap. 18.

1. Three consecutive revolute joint axes intersect at a common point, as in a spherical wrist.
2. Three consecutive revolute joint axes are parallel.

Closed-form solution approaches are generally divided into algebraic and geometric methods.

Algebraic Methods

Algebraic methods involve identifying the significant equations containing the joint variables and manipulating them into a soluble form. A common strategy is reduction to a transcendental equation in a single variable such as,

$$C_1 \cos \theta_i + C_2 \sin \theta_i + C_3 = 0, \quad (2.47)$$

where C_1 , C_2 , and C_3 are constants. The solution to such an equation is

$$\theta_i = 2 \tan^{-1} \left(\frac{C_2 \pm \sqrt{C_2^2 - C_3^2 + C_1^2}}{C_1 - C_3} \right). \quad (2.48)$$

Special cases in which one or more of the constants are zero are also common.

Reduction to a pair of equations having the form,

$$C_1 \cos \theta_i + C_2 \sin \theta_i + C_3 = 0, \quad (2.49)$$

$$C_1 \sin \theta_i - C_2 \cos \theta_i + C_4 = 0, \quad (2.50)$$

is another particularly useful strategy because only one solution results,

$$\theta_i = \text{Atan2}(-C_1 C_4 - C_2 C_3, C_2 C_4 - C_1 C_3). \quad (2.51)$$

Geometric Methods

Geometric methods involve identifying points on the manipulator relative to which position and/or orientation can be expressed as a function of a reduced set of the joint variables. This often amounts to decomposing the spatial problem into separate planar problems. The resulting equations are solved using algebraic manipulation. The two sufficient conditions for existence of a closed-form solution for a six-degree-of-freedom manipulator that are listed above enable the decomposition of the problem into inverse position kinematics and inverse orientation kinematics. This is the decomposition into regional and orientation structures discussed in Sect. 2.5, and the solution is found by rewriting (2.46),

$${}^0\mathbf{T}_6 {}^6\mathbf{T}_5 {}^5\mathbf{T}_4 {}^4\mathbf{T}_3 = {}^0\mathbf{T}_1 {}^1\mathbf{T}_2 {}^2\mathbf{T}_3. \quad (2.52)$$

The example manipulator in Fig. 2.3 has this structure, and its regional structure is commonly known as an articulated or anthropomorphic arm or an elbow manipulator. The solution to the inverse position kinematics problem for such a structure is summarized in Table 2.9. Because there are two solutions for θ_1 and likewise two solutions for both θ_2 and θ_3 corresponding to each θ_1 solution, there are a total of four solutions to the inverse position kinematics problem of the articulated arm manipulator. The orientation structure is simply a spherical wrist, and the corresponding solution to the inverse orientation kinematics problem is summarized in Table 2.10. Two solutions for θ_5 are given in Table 2.10, but only one solution for both θ_4 and θ_6 corresponds to each. Thus, the inverse orientation kinematics problem of a spherical wrist has two solutions. Combining the regional and orientation structures, the total number of inverse kinematics solutions for the manipulator in Fig. 2.3 is eight.

2.7.2 Numerical Methods

Unlike the algebraic and geometric methods used to find closed-form solutions, numerical methods are not robot dependent, so they can be applied to any kine-

matic structure. The disadvantages of numerical methods are that they can be slower and in some cases, they do not allow computation of all possible solutions. For a six-degree-of-freedom serial-chain manipulator with only revolute and prismatic joints, the translation and rotation equations can always be reduced to a polynomial in a single variable of degree not greater than 16 [2.37]. Thus, such a manipulator can have as many as 16 real solutions to the inverse kinematics problem [2.38]. Since closed-form solution of a polynomial equation is only possible if the polynomial is of degree four or less, it follows that many manipulator geometries are not soluble in closed form. In general, a greater number of nonzero geometric parameters corresponds to a polynomial of higher degree in the reduction. For such manipulator structures, the most common numerical methods can be divided into categories of symbolic elimination methods, continuation methods, and iterative methods.

Symbolic Elimination Methods

Symbolic elimination methods involve analytical manipulations to eliminate variables from the system of nonlinear equations to reduce it to a smaller set of equations. *Raghavan* and *Roth* [2.39] used dialytic elimination to reduce the inverse kinematics problem of a general 6R serial-chain manipulator to a polyno-

Table 2.9 Inverse position kinematics of the articulated arm within the example serial chain manipulator in Fig. 2.3

$$\begin{aligned} \theta_1 &= \text{Atan2}({}^0p_6^y, {}^0p_6^x) \\ &\text{or } \text{Atan2}(-{}^0p_6^y, -{}^0p_6^x) \\ \theta_3 &= -\text{Atan2}\left(D, \pm\sqrt{1-D^2}\right), \\ \text{where } D &:= \frac{({}^0p_6^x)^2 + ({}^0p_6^y)^2 + ({}^0p_6^z)^2 - a_3^2 - d_4^2}{2a_3d_4}, \\ \theta_2 &= \text{Atan2}\left({}^0p_6^z, \sqrt{({}^0p_6^x)^2 + ({}^0p_6^y)^2}\right) \\ &\quad - \text{Atan2}(d_4 \cos \theta_3, a_3 - d_4 \sin \theta_3) \end{aligned}$$

Table 2.10 Inverse orientation kinematics of the spherical wrist within the example serial chain manipulator in Fig. 2.3, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$

$$\begin{aligned} \theta_5 &= \text{Atan2}\left(\pm\sqrt{1 - (r_{13}s_{\theta_1} - r_{23}c_{\theta_1})^2}, r_{13}s_{\theta_1} - r_{23}c_{\theta_1}\right) \\ \theta_4 &= \text{Atan2}\left(\mp(r_{13}c_{\theta_1} + r_{23}s_{\theta_1})s_{(\theta_2+\theta_3)} \mp r_{33}c_{(\theta_2+\theta_3)}, \right. \\ &\quad \left. \pm(r_{13}c_{\theta_1} + r_{23}s_{\theta_1})c_{(\theta_2+\theta_3)} \mp r_{23}s_{(\theta_2+\theta_3)}\right) \\ \theta_6 &= \text{Atan2}\left(\pm(r_{12}s_{\theta_1} + r_{22}c_{\theta_1}), \pm(r_{11}s_{\theta_1} - r_{21}c_{\theta_1})\right), \\ &\text{where the } \pm \text{ choice for } \theta_5 \text{ dictates all of the subsequent } \pm \\ &\text{and } \mp \text{ for } \theta_4 \text{ and } \theta_6. \end{aligned}$$

mial of degree 16 and to find all possible solutions. The roots provide solutions for one of the joint variables, while the other variables are computed by solving linear systems. *Manocha* and *Canny* [2.40] improved the numerical properties of this technique by reformulating the problem as a generalized eigenvalue problem. An alternative approach to elimination makes use of Gröbner bases [2.41, 42].

Continuation Methods

Continuation methods involve tracking a solution path from a start system with known solutions to a target system whose solutions are sought as the start system is transformed into the target system. These techniques have been applied to inverse kinematics problems [2.43], and special properties of polynomial systems can be exploited to find all possible solutions [2.44].

Iterative Methods

A number of different iterative methods can be employed to solve the inverse kinematics problem. Most

of them converge to a single solution based on an initial guess, so the quality of that guess greatly impacts the solution time. Newton–Raphson methods provide a fundamental approach that uses a first-order approximation of the original equations. *Pieper* [2.34] was among the first to apply the method to inverse kinematics, and others have followed [2.45, 46]. Optimization approaches formulate the problem as a nonlinear optimization problem and employ search techniques to move from an initial guess to a solution [2.47, 48]. Resolved motion rate control converts the problem to a differential equation [2.49], and a modified predictor–corrector algorithm can be used to perform the joint velocity integration [2.50]. Control-theory-based methods cast the differential equation into a control problem [2.51]. Interval analysis [2.52] is perhaps one of the most promising iterative methods because it offers rapid convergence to a solution and can be used to find all possible solutions. For complex mechanisms, the damped least-squares approach [2.53] is particularly attractive, and more detail is provided in Chap. 10.

2.8 Forward Instantaneous Kinematics

The forward instantaneous kinematics problem for a serial-chain manipulator is: given the positions of all members of the chain and the rates of motion about all the joints, find the total velocity of the end-effector. Here the rate of motion about the joint is the angular velocity of rotation about a revolute joint or the translational velocity of sliding along a prismatic joint. The total velocity of a member is the velocity of the origin of the coordinate frame fixed to it combined with its angular velocity. That is, the total velocity has six independent components and therefore, completely represents the velocity field of the member. It is important to note that this problem definition includes an assumption that the pose of the mechanism is completely known. In most situations, this means that either the forward or inverse position kinematics problem must be solved before the forward instantaneous kinematics problem can be addressed. The same is true of the inverse instantaneous kinematics problem discussed in the following section. The forward instantaneous kinematics problem is important when doing acceleration analysis for the purpose of studying dynamics. The total velocities of the members are needed for the computation of Coriolis and centripetal acceleration components.

2.8.1 Jacobian

Differentiation with respect to time of the forward position kinematics equations yields a set of equations of the form

$${}^k v_N = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}, \quad (2.53)$$

where ${}^k v_N$ is the spatial velocity of the end-effector expressed in any frame k , $\dot{\mathbf{q}}$ is an n -dimensional vector composed of the joint rates, and $\mathbf{J}(\mathbf{q})$ is a $6 \times n$ matrix whose elements are, in general, nonlinear functions of \mathbf{q} . $\mathbf{J}(\mathbf{q})$ is called the Jacobian matrix of this algebraic system and is expressed relative to the same coordinate frame as the spatial velocity ${}^k v_N$ [2.54]. Alternately, (2.53) can be expressed as

$${}^k v_N = [\mathbf{J}_1 \ \mathbf{J}_2 \ \cdots \ \mathbf{J}_N] \dot{\mathbf{q}}, \quad (2.54)$$

where N is the number of joints (each with possibly more than 1 degree-of-freedom) and \mathbf{J}_i provides the column(s) of $\mathbf{J}(\mathbf{q})$ which correspond(s) to \dot{q}_i . If the joint positions are known, (2.53) yields six linear algebraic equations in the joint rates. If the joint rates are given,

a solution of (2.53) is a solution of the forward instantaneous kinematics problem. Note that $\mathbf{J}(\mathbf{q})$ can be regarded as a known matrix for this purpose provided all the joint positions are known.

Algorithm 2.1 Jacobian Computation Algorithm for a Serial-Chain Mechanism

inputs: ${}^k\mathbf{X}_N, {}^N\mathbf{X}_{N-1}, \dots, {}^i\mathbf{X}_{i-1}, \dots, {}^2\mathbf{X}_1$
output: \mathbf{J}

```

 $\mathbf{X} = {}^k\mathbf{X}_N$ 
for  $i = N$  to 1 do
   $\mathbf{J}_i = \mathbf{X} \Phi_i$ 
  if  $i > 1$  then
     $\mathbf{X} = \mathbf{X} {}^i\mathbf{X}_{i-1}$ 
  end if
end for

```

Using the spatial vector notation briefly introduced in Sect. 2.2.6 and explained in detail in Sect. 3.2, the Jacobian can be easily computed from the free modes Φ_i

of the joints and the associated spatial transforms ${}^j\mathbf{X}_i$.

$$\mathbf{J}_i = {}^k\mathbf{X}_i \Phi_i. \quad (2.55)$$

To understand why this holds, note that Φ_i describes the spatial velocities created by joint i in local coordinates and ${}^k\mathbf{X}_i$ transforms spatial velocities expressed in frame i to frame k . The quantities \mathbf{J}_i can be efficiently computed from ${}^k\mathbf{X}_N$ and the link-to-link transforms ${}^i\mathbf{X}_{i-1}$. Algorithm 2.1 contains an algorithm for computing the columns of the Jacobian in this manner. Table 3.1 provides efficient methods to carry out the multiplications required in this algorithm which exploit the structure of spatial transformation matrices. Note that the quantity ${}^k\mathbf{X}_N$ can be computed with forward kinematics and each ${}^i\mathbf{X}_{i-1}$ can be computed with simple joint kinematics. Thus, use of the algorithm in Alg. 2.1 simplifies the problem of forward instantaneous kinematics to one of forward standard kinematics. Additional information about the Jacobian can be found in Chap. 10.

2.9 Inverse Instantaneous Kinematics

The important problem from the point of view of robotic coordination is the inverse instantaneous kinematics problem. More information on robot coordination can be found in Chaps. 7 and 8. The inverse instantaneous kinematics problem for a serial chain manipulator is: given the positions of all members of the chain and the total velocity of the end-effector, find the rates of motion of all joints. When controlling a movement of an industrial robot that operates in the point-to-point mode, it is not only necessary to compute the final joint positions needed to assume the desired final hand position. It is also necessary to generate a smooth trajectory for motion between the initial and final positions. There are, of course, an infinite number of possible trajectories for this purpose. However, the most straightforward and successful approach employs algorithms based on the solution of the inverse instantaneous kinematics problem. This technique originated in the work of *Whitney* [2.55] and of *Pieper* [2.34].

2.9.1 Inverse Jacobian

In order to solve the linear system of equations in the joint rates obtained by decomposing (2.53) into its com-

ponent equations when \mathbf{v}_N is known, it is necessary to invert the Jacobian matrix. The equation becomes

$$\dot{\mathbf{q}} = \mathbf{J}^{-1}(\mathbf{q}) \mathbf{v}_N. \quad (2.56)$$

Since \mathbf{J} is a 6×6 matrix, numerical inversion is not very attractive. It is quite possible for \mathbf{J} to become singular ($|\mathbf{J}| = 0$), in which case the inverse does not exist. More information on singularities can be found in Chaps. 4 and 18. Even when the Jacobian matrix does not become singular, it may become ill-conditioned, leading to degraded performance in significant portions of the manipulator's workspace. Most industrial robot geometries are simple enough that the Jacobian matrix can be inverted analytically, leading to a set of explicit equations for the joint rates [2.56–58]. This greatly reduces the number of operations needed as compared to numerical inversion. For more complex manipulator geometries, though, numerical inversion is the only solution option. The Jacobian of a redundant manipulator is not square, so it cannot be inverted. Chapter 10 discusses how various pseudoinverses can be used in such cases.

2.10 Static Wrench Transmission

A general force system can be shown to be equivalent to a single force together with a moment acting about its line of action. This is called a wrench. There is a deep isometry between the geometries of systems of wrench axes and that of systems of instantaneous screw axes [2.59]. Static wrench analysis of a manipulator establishes the relationship between wrenches applied to the end-effector and forces/torques applied to the joints. This is essential for controlling a manipulator's interactions with its environment. Examples include tasks involving fixed or quasi-fixed workpieces such as inserting a component in place with a specified force and tightening a nut to a prescribed torque. More information can be found in Chaps. 9 and 37. Through the principle of virtual work, the relationship between wrenches applied to the end-effector and forces/torques applied to the joints can be shown to be

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{f}, \quad (2.57)$$

where $\boldsymbol{\tau}$ is the n -dimensional vector of applied joint forces/torques for an n -degree-of-freedom manipulator and \mathbf{f} is the spatial force vector

$$\mathbf{f} = \begin{pmatrix} \mathbf{n} \\ \mathbf{f} \end{pmatrix}, \quad (2.58)$$

in which \mathbf{n} and \mathbf{f} are the vectors of torques and forces, respectively, applied to the end-effector, both expressed in the coordinate frame relative to which the Jacobian is also expressed. Thus, in the same way the Jacobian maps the joint rates to the spatial velocity of the end-effector, its transpose maps the wrenches applied to the end-effector to the equivalent joint forces/torques. As in the velocity case, when the Jacobian is not square, the inverse relationship is not uniquely defined.

2.11 Conclusions and Further Reading

This chapter presents an overview of how the fundamentals of kinematics can be applied to robotic mechanisms. The topics include various representations of the position and orientation of a rigid body in space, the freedom of motion and accompanying mathematical models of joints, a geometric representation that describes the bodies and joints of a robotic mechanism, the workspace of a manipulator, the problems of forward and inverse kinematics, the problems of forward and inverse instantaneous kinematics including the definition of the Jacobian, and finally the transmission of static wrenches. This chapter is certainly not a comprehensive account of robot kinematics. Fortunately, a number of excellent texts provide a broad introduction to robotics with significant focus on kinematics [2.17, 27, 29, 30, 51, 60–64].

From a historical perspective, robotics fundamentally changed the nature of the field of mechanism kinematics. Before the first work on the generation of coordination equations for robots [2.34, 55], the focus of the field was almost entirely on single-degree-of-freedom mechanisms. This is why robotics, following on from the advent of digital computing, led to a renaissance of work in mechanism kinematics. More details can be found in Chap. 4. The evolution of the field has continued as it has broadened from the study of simple serial chains for industrial robots, the focus of the analysis in this chapter, to parallel machines (Chap. 18), human-like grippers (Chap. 19), robotic vehicles (Chaps. 17 and 24–26), and even small-scale robots (Chap. 27).

3. Dynamics

Roy Featherstone, David E. Orin

The dynamic equations of motion provide the relationships between actuation and contact forces acting on robot mechanisms, and the acceleration and motion trajectories that result. Dynamics is important for mechanical design, control, and simulation. A number of algorithms are important in these applications, and include computation of the following: *inverse dynamics*, *forward dynamics*, the *joint-space inertia matrix*, and the *operational-space inertia matrix*. This chapter provides efficient algorithms to perform each of these calculations on a rigid-body model of a robot mechanism. The algorithms are presented in their most general form and are applicable to robot mechanisms with general connectivity, geometry, and joint types. Such mechanisms include fixed-base robots, mobile robots, and parallel robot mechanisms.

In addition to the need for computational efficiency, algorithms should be formulated with a compact set of equations for ease of development and implementation. The use of spatial notation has been very effective in this regard, and is used in presenting the dynamics algorithms. Spatial vector algebra is a concise vector notation for describing rigid-body velocity, acceleration, inertia, etc., using six-dimensional (6-D) vectors and tensors.

The goal of this chapter is to introduce the reader to the subject of robot dynamics and to provide the reader with a rich set of algorithms, in a compact form, that they may apply to their particular robot mechanism. These algorithms are presented in tables for ready access.

3.1 Overview

Robot dynamics provides the relationships between actuation and contact forces, and the acceleration and motion trajectories that result. The dynamic equations of motion provide the basis for a number of computational algorithms that are useful in mechanical design, control, and simulation. A growing area of their use is in computer animation of mobile systems, especially using human and humanoid models. In this Chapter, the fundamental dynamic relationships for robot mechanisms are presented, along with efficient algorithms for the most common computations. Spatial vector notation, a concise representation which makes use of **6-D** vectors and tensors, is used in the algorithms.

This chapter presents efficient low-order algorithms for four major computations:

1. Inverse dynamics, in which the required joint actuator torques/forces are computed from a specification of the robot's trajectory (position, velocity, and acceleration),
2. Forward dynamics in which the applied joint actuator torques/forces are specified and the joint accelerations are to be determined,
3. The joint-space inertia matrix, which maps the joint accelerations to the joint torques/forces, and
4. The operational-space inertia matrix, which maps task accelerations to task forces in operational or Cartesian space.

Inverse dynamics is used in feedforward control and trajectory planning. Forward dynamics is required for simulation. The joint-space inertia (mass) matrix is used in analysis, in feedback control to linearize the dynamics, and is an integral part of many forward dynamics formulations. The operational-space inertia matrix is used in control at the task or end-effector level.

3.1.1 Spatial Vector Notation

Section 3.2 presents the spatial vector notation, which is used to express the algorithms in this chapter in a clear and concise manner. It was originally developed by *Featherstone* [3.1] to provide a concise vector notation for describing rigid-body velocity, acceleration,

inertia, etc., using **6-D** vectors and tensors. Section 3.2 explains the meanings of spatial vectors and operators, and provides a detailed tabulation of the correspondence between spatial and standard three-dimensional (**3-D**) quantities and operators, so that the algorithms in the later sections can be understood. Formulae for efficient computer implementation of spatial arithmetic are also provided. Effort is taken in the discussion of spatial vectors to distinguish between the coordinate vectors and the quantities they represent. This illuminates some of the important characteristics of spatial vectors.

3.1.2 Canonical Equations

The dynamic equations of motion are provided in Sect. 3.3 in two fundamental forms: the joint-space formulation and the operational-space formulation. The terms in the joint-space formulation have traditionally been derived using a Lagrangian approach in which they are developed independently of any reference coordinate frame. The Lagrange formulation provides a description of the relationship between the joint actuator forces and the motion of the mechanism, and fundamentally operates on the kinetic and potential energy in the system. The resulting joint-space formulation has a number of notable properties that have proven useful for developing control algorithms. The equations to relate the terms in the joint-space and operational-space formulations, along with an impact model, are also provided in this section.

3.1.3 Dynamic Models of Rigid-Body Systems

The algorithms in this chapter are model-based and require a data structure describing a robot mechanism as one of their input arguments. Section 3.4 gives a description of the components of this model: a connectivity graph, link geometry parameters, link inertia parameters, and a set of joint models. The description of the connectivity is general so that it covers both kinematic trees and closed-loop mechanisms. Kinematic trees and the spanning tree for a closed-loop mechanism share a common notation. In order to describe

the link and joint geometry, two coordinate frames are associated with each joint, one each attached to the *predecessor* and *successor* links. These frames are defined to be compatible with the modified Denavit–Hartenberg convention of *Craig* [3.2] for serial mechanisms containing single-degree-of-freedom (DOF) joints, but are nevertheless applicable to general rigid-body systems containing general multi-DOF joints. The relationship between connected links is described using the general joint model of *Roberson* and *Schwertassek* [3.3]. A humanoid robot is given as an example to illustrate the link and joint numbering scheme, as well as the assignment of coordinate frames to describe the links and joints. The example includes a floating base, and revolute, universal, and spherical joints.

3.1.4 Kinematic Trees

The algorithms presented in Sect. 3.5 calculate the inverse dynamics, forward dynamics, joint-space inertia matrix, and operational-space inertia matrix for any robot mechanism that is a kinematic tree. An $O(n)$ algorithm for inverse dynamics is provided, where n is the number of degrees of freedom in the mechanism. It uses a Newton–Euler formulation of the problem, and is based on the very efficient recursive Newton–Euler algorithm (RNEA) of *Luh et al.* [3.4]. Two algorithms are provided for forward dynamics. The first is the $O(n)$ articulated-body algorithm (ABA) which was developed by *Featherstone* [3.1]. The second is the $O(n^2)$ composite-rigid-body algorithm (CRBA), developed by *Walker* and *Orin* [3.5], to compute the joint-space inertia matrix (JSIM). This matrix, together with a vector computed using the RNEA, provide the coefficients of the equation of motion, which can then be solved directly for the accelerations [3.5]. The operational-space inertia matrix (OSIM) is a kind of articulated-body inertia, and two algorithms are given to calculate it. The

first uses the basic definition of the OSIM, and the second is a straightforward $O(n)$ algorithm which is based on efficient solution of the forward dynamics problem. The inputs, outputs, model data, and pseudocode for each algorithm are summarized in tables for ready access.

3.1.5 Kinematic Loops

The above algorithms apply only to mechanisms having the connectivity of kinematic trees, including unbranched kinematic chains. A final algorithm is provided in Sect. 3.6 for the forward dynamics of closed-loop systems, including parallel robot mechanisms. The algorithm makes use of the dynamic equations of motion for a spanning tree of the closed-loop system, and supplements these with loop-closure constraint equations. Three different methods are outlined to solve the resulting linear system of equations. Method 2 is particularly useful if $n \gg n^c$, where n^c is the number of constraints due to the loop-closing joints. This method offers the opportunity to use $O(n)$ algorithms on the spanning tree [3.6]. The section ends with an efficient algorithm to compute the loop-closure constraints by transforming them to a single coordinate system. Since the loop-closure constraint equations are applied at the acceleration level, standard *Baumgarte* stabilization [3.7] is used to prevent the accumulation of position and velocity errors in the loop-closure constraints.

The final section in this chapter provides a conclusion and suggestions for further reading. The area of robot dynamics has been, and continues to be, a very rich area of investigation. This section outlines the major contributions that have been made in the area and the work most often cited. Unfortunately, space does not permit us to provide a comprehensive review of the extensive literature in the area.

3.2 Spatial Vector Notation

There is no single standard notation for robot dynamics. The notations currently in use include 3-D vectors, 4×4 matrices, and several types of 6-D vector: screws, motors, Lie algebra elements, and spatial vectors. Six-dimensional vector notations are generally the best, being more compact than 3-D vectors, and more powerful than 4×4 matrices. We therefore use 6-D vectors throughout this chapter. In particular, we shall use the spatial vector algebra described in [3.8]. This section provides a brief summary of spatial vectors. Descriptions of 4×4 matrix nota-

tions can be found in [3.2, 9], and descriptions of other 6-D vector notations can be found in [3.10–12].

In this handbook, vectors are usually denoted by bold italic letters (e.g., \mathbf{f} , \mathbf{v}). However, to avoid a few name clashes, we shall use upright bold letters to denote spatial vectors (e.g., \mathbf{f} , \mathbf{v}). Note that this applies only to vectors, not tensors. Also, *in this section only*, we will underline coordinate vectors to distinguish them from the vectors that they represent (e.g., \underline{v} and \underline{v} , representing \mathbf{v} and \mathbf{v}).

Fig.3.1a,b Plücker basis vectors for motions (a) and forces (b)

3.2.1 Motion and Force

For mathematical reasons, it is useful to distinguish between those vectors that describe the motions of rigid bodies, and those that describe the forces acting upon them. We therefore place motion vectors in a vector space called M^6 , and force vectors in a space called F^6 . (The superscripts indicate the dimension.) Motion vectors describe quantities like velocity, acceleration, infinitesimal displacement, and directions of motion freedom; force vectors describe force, momentum, contact normals, and so on.

3.2.2 Basis Vectors

Suppose that \mathbf{v} is a 3-D vector, and that $\underline{\mathbf{v}} = (v_x, v_y, v_z)^T$ is the Cartesian coordinate vector that represents \mathbf{v} in the orthonormal basis $\{\hat{x}, \hat{y}, \hat{z}\}$. The relationship between \mathbf{v} and $\underline{\mathbf{v}}$ is then given by the formula

$$\mathbf{v} = \hat{x}v_x + \hat{y}v_y + \hat{z}v_z.$$

This same idea applies also to spatial vectors, except that we use Plücker coordinates instead of Cartesian coordinates, and a Plücker basis instead of an orthonormal basis.

Plücker coordinates were introduced in Sect. 2.2.6, but the basis vectors are shown in Fig. 3.1. There are 12 basis vectors in total: six for motion vectors and six for forces. Given a Cartesian coordinate frame, O_{xyz} , the Plücker basis vectors are defined as follows: three unit rotations about the directed lines Ox , Oy , and Oz , denoted by \mathbf{d}_{Ox} , \mathbf{d}_{Oy} , and \mathbf{d}_{Oz} , three unit translations in the directions x , y , and z , denoted by \mathbf{d}_x , \mathbf{d}_y , and \mathbf{d}_z , three unit couples about the x , y , and z directions, denoted by \mathbf{e}_x , \mathbf{e}_y , and \mathbf{e}_z , and three unit forces along the lines Ox , Oy , and Oz , denoted by \mathbf{e}_{Ox} , \mathbf{e}_{Oy} , and \mathbf{e}_{Oz} .

3.2.3 Spatial Velocity and Force

Given any point O , the velocity of a rigid body can be described by a pair of 3-D vectors, $\boldsymbol{\omega}$ and \mathbf{v}_O , which

specify the body's angular velocity and the linear velocity of the body-fixed point currently at O . Note that \mathbf{v}_O is not the velocity of O itself, but the velocity of the body-fixed point that happens to coincide with O at the current instant.

The velocity of this same rigid body can also be described by a single spatial motion vector, $\mathbf{v} \in M^6$. To obtain \mathbf{v} from $\boldsymbol{\omega}$ and \mathbf{v}_O , we first introduce a Cartesian frame, O_{xyz} , with its origin at O . This frame defines a Cartesian coordinate system for $\boldsymbol{\omega}$ and \mathbf{v}_O , and also a Plücker coordinate system for \mathbf{v} . Given these coordinate systems, it can be shown that

$$\mathbf{v} = \mathbf{d}_{Ox}\omega_x + \mathbf{d}_{Oy}\omega_y + \mathbf{d}_{Oz}\omega_z + \mathbf{d}_x v_{Ox} + \mathbf{d}_y v_{Oy} + \mathbf{d}_z v_{Oz}, \quad (3.1)$$

where ω_x, \dots, v_{Oz} are the Cartesian coordinates of $\boldsymbol{\omega}$ and \mathbf{v}_O in O_{xyz} . Thus, the Plücker coordinates of \mathbf{v} are the Cartesian coordinates of $\boldsymbol{\omega}$ and \mathbf{v}_O . The coordinate vector representing \mathbf{v} in O_{xyz} can be written

$$\underline{\mathbf{v}}_O = \begin{pmatrix} \omega_x \\ \vdots \\ v_{Oz} \end{pmatrix} = \begin{pmatrix} \boldsymbol{\omega} \\ \underline{\mathbf{v}}_O \end{pmatrix}. \quad (3.2)$$

The notation on the far right of this equation is simply a convenient abbreviation of the list of Plücker coordinates.

The definition of spatial force is very similar. Given any point O , any system of forces acting on a single rigid body is equivalent to a single force \mathbf{f} acting on a line passing through O , together with a pure couple, \mathbf{n}_O , which is the moment of the force system about O . Thus, the two vectors \mathbf{f} and \mathbf{n}_O describe the force acting on a rigid body in much the same way that $\boldsymbol{\omega}$ and \mathbf{v}_O describe its velocity. This same force can also be described by a single spatial force vector, $\mathbf{f} \in F^6$. Introducing the frame O_{xyz} , as before, it can be shown that

$$\mathbf{f} = \mathbf{e}_x n_{Ox} + \mathbf{e}_y n_{Oy} + \mathbf{e}_z n_{Oz} + \mathbf{e}_{Ox} f_x + \mathbf{e}_{Oy} f_y + \mathbf{e}_{Oz} f_z, \quad (3.3)$$

where n_{Ox}, \dots, f_z are the Cartesian coordinates of \mathbf{n}_O and \mathbf{f} in O_{xyz} . The coordinate vector representing \mathbf{f} in O_{xyz} can then be written

$$\underline{\mathbf{f}}_O = \begin{pmatrix} n_{Ox} \\ \vdots \\ f_z \end{pmatrix} = \begin{pmatrix} \underline{\mathbf{n}}_O \\ \underline{\mathbf{f}} \end{pmatrix}. \quad (3.4)$$

Again, these are the Plücker coordinates of \mathbf{f} in O_{xyz} , and the notation on the far right is simply a convenient abbreviation of the list of Plücker coordinates.

3.2.4 Addition and Scalar Multiplication

Spatial vectors behave in the obvious way under addition and scalar multiplication. For example, if \mathbf{f}_1 and \mathbf{f}_2 both act on the same rigid body, then their resultant is $\mathbf{f}_1 + \mathbf{f}_2$; if two different bodies have velocities of \mathbf{v}_1 and \mathbf{v}_2 , then the velocity of the second body relative to the first is $\mathbf{v}_2 - \mathbf{v}_1$; and if \mathbf{f} denotes a force of 1 N acting along a particular line in space, then $\alpha \mathbf{f}$ denotes a force of α N acting along the same line.

3.2.5 Scalar Product

A scalar product is defined between any two spatial vectors, provided that one of them is a motion and the other a force. Given any $\mathbf{m} \in M^6$ and $\mathbf{f} \in F^6$, the scalar product can be written either $\mathbf{f} \cdot \mathbf{m}$ or $\mathbf{m} \cdot \mathbf{f}$, and expresses the work done by a force \mathbf{f} acting on a body with motion \mathbf{m} . Expressions like $\mathbf{f} \cdot \mathbf{f}$ and $\mathbf{m} \cdot \mathbf{m}$ are not defined. If $\underline{\mathbf{m}}$ and $\underline{\mathbf{f}}$ are coordinate vectors representing \mathbf{m} and \mathbf{f} in the same coordinate system, then

$$\mathbf{m} \cdot \mathbf{f} = \underline{\mathbf{m}}^T \underline{\mathbf{f}}. \quad (3.5)$$

3.2.6 Coordinate Transforms

Motion and force vectors obey different transformation rules. Let A and B be two coordinate frames, each defining a coordinate system of the same name; and let $\underline{\mathbf{m}}_A$, $\underline{\mathbf{m}}_B$, $\underline{\mathbf{f}}_A$, and $\underline{\mathbf{f}}_B$ be coordinate vectors representing the spatial vectors $\mathbf{m} \in M^6$ and $\mathbf{f} \in F^6$ in A and B coordinates, respectively. The transformation rules are then

$$\underline{\mathbf{m}}_B = {}^B X_A \underline{\mathbf{m}}_A \quad (3.6)$$

and

$$\underline{\mathbf{f}}_B = {}^B X_A^F \underline{\mathbf{f}}_A, \quad (3.7)$$

where ${}^B X_A$ and ${}^B X_A^F$ are the coordinate transformation matrices from A to B for motion and force vectors, respectively. These matrices are related by the identity

$${}^B X_A^F \equiv ({}^B X_A)^{-T} \equiv ({}^A X_B)^T. \quad (3.8)$$

Suppose that the position and orientation of frame A relative to frame B is described by a position vector ${}^B \underline{\mathbf{p}}_A$ and a 3×3 rotation matrix ${}^B R_A$, as described in Sect. 2.2. The formula for ${}^B X_A$ is then

$$\begin{aligned} {}^B X_A &= \begin{pmatrix} \mathbf{1} & \mathbf{0} \\ S({}^B \underline{\mathbf{p}}_A) & \mathbf{1} \end{pmatrix} \begin{pmatrix} {}^B R_A & \mathbf{0} \\ \mathbf{0} & {}^B R_A \end{pmatrix} \\ &= \begin{pmatrix} {}^B R_A & \mathbf{0} \\ S({}^B \underline{\mathbf{p}}_A) {}^B R_A & {}^B R_A \end{pmatrix}, \end{aligned} \quad (3.9)$$

and its inverse is

$${}^A X_B = \begin{pmatrix} {}^A R_B & \mathbf{0} \\ \mathbf{0} & {}^A R_B \end{pmatrix} \begin{pmatrix} \mathbf{1} & \mathbf{0} \\ -S({}^B \underline{\mathbf{p}}_A) & \mathbf{1} \end{pmatrix}. \quad (3.10)$$

The quantity $S(\underline{\mathbf{p}})$ is the skew-symmetric matrix that satisfies $S(\underline{\mathbf{p}})\underline{\mathbf{v}} = \underline{\mathbf{p}} \times \underline{\mathbf{v}}$ for any 3-D vector $\underline{\mathbf{v}}$. It is defined by the equation

$$S(\underline{\mathbf{p}}) = \begin{pmatrix} 0 & -p_z & p_y \\ p_z & 0 & -p_x \\ -p_y & p_x & 0 \end{pmatrix}. \quad (3.11)$$

3.2.7 Vector Products

There are two vector (cross) products defined on spatial vectors. The first takes two motion-vector arguments, and produces a motion-vector result. It is defined by the formula

$$\begin{aligned} \underline{\mathbf{m}}_1 \times \underline{\mathbf{m}}_2 &= \begin{pmatrix} \underline{m}_1 \\ \underline{m}_{1O} \end{pmatrix} \times \begin{pmatrix} \underline{m}_2 \\ \underline{m}_{2O} \end{pmatrix} \\ &= \begin{pmatrix} \underline{m}_1 \times \underline{m}_2 \\ \underline{m}_1 \times \underline{m}_{2O} + \underline{m}_{1O} \times \underline{m}_2 \end{pmatrix}. \end{aligned} \quad (3.12)$$

The second takes a motion vector as left-hand argument and a force vector as right-hand argument, and produces a force-vector result. It is defined by the formula

$$\begin{aligned} \underline{\mathbf{m}} \times \underline{\mathbf{f}} &= \begin{pmatrix} \underline{m} \\ \underline{m}_O \end{pmatrix} \times \begin{pmatrix} \underline{f}_O \\ \underline{f} \end{pmatrix} \\ &= \begin{pmatrix} \underline{m} \times \underline{f}_O + \underline{m}_O \times \underline{f} \\ \underline{m} \times \underline{f} \end{pmatrix}. \end{aligned} \quad (3.13)$$

These products arise in differentiation formulae.

It is possible to define a spatial cross-product operator, in analogy with (3.11), as follows

$$S(\underline{\mathbf{m}}) = \begin{pmatrix} S(\underline{m}) & \mathbf{0} \\ S(\underline{m}_O) & S(\underline{m}) \end{pmatrix}, \quad (3.14)$$

in which case

$$\underline{\mathbf{m}}_1 \times \underline{\mathbf{m}}_2 = S(\underline{\mathbf{m}}_1) \underline{\mathbf{m}}_2, \quad (3.15)$$

but

$$\underline{\mathbf{m}} \times \underline{\mathbf{f}} = -S(\underline{\mathbf{m}})^T \underline{\mathbf{f}}. \quad (3.16)$$

Observe that $S(\underline{\mathbf{m}})$ maps motion vectors to motion vectors, but $S(\underline{\mathbf{m}})^T$ maps force vectors to force vectors.

3.2.8 Differentiation

The derivative of a spatial vector is defined by

$$\frac{d}{dx}\mathbf{s}(x) = \lim_{\delta x \rightarrow 0} \frac{\mathbf{s}(x + \delta x) - \mathbf{s}(x)}{\delta x}, \quad (3.17)$$

where \mathbf{s} here stands for any spatial vector. The derivative is a spatial vector of the same kind (motion or force) as that being differentiated.

The formula for differentiating a spatial coordinate vector in a moving coordinate system is

$$\left(\frac{d}{dt}\mathbf{s}\right)_A = \frac{d}{dt}\mathbf{s}_A + \mathbf{v}_A \times \mathbf{s}_A, \quad (3.18)$$

where \mathbf{s} is any spatial vector, $d\mathbf{s}/dt$ is the time derivative of \mathbf{s} , A is the moving coordinate system, $(d\mathbf{s}/dt)_A$ is the coordinate vector that represents $d\mathbf{s}/dt$ in A coordinates, \mathbf{s}_A is the coordinate vector that represents \mathbf{s} in A coordinates, $d\mathbf{s}_A/dt$ is the time derivative of \mathbf{s}_A (which is the componentwise derivative, since \mathbf{s}_A is a coordinate vector), and \mathbf{v}_A is the velocity of the A coordinate frame, expressed in A coordinates.

The time derivative of a spatial vector that changes only because it is moving is given by

$$\frac{d}{dt}\mathbf{s} = \mathbf{v} \times \mathbf{s}, \quad (3.19)$$

where \mathbf{v} is the velocity of \mathbf{s} . This formula is useful for differentiating quantities that do not change in their own right, but are attached to moving rigid bodies (e.g., joint axis vectors).

3.2.9 Acceleration

Spatial acceleration is defined as the rate of change of spatial velocity. Unfortunately, this means that spatial acceleration differs from the classical textbook definition of rigid-body acceleration, which we shall call *classical acceleration*. Essentially, the difference can be summarized as follows

$$\mathbf{a} = \left(\frac{\dot{\omega}}{\dot{v}_O}\right) \quad \text{and} \quad \mathbf{a}' = \left(\frac{\dot{\omega}}{\dot{v}'_O}\right), \quad (3.20)$$

where \mathbf{a} is the spatial acceleration, \mathbf{a}' is the classical acceleration, \dot{v}_O is the derivative of v_O taking O to be fixed in space, and \dot{v}'_O is the derivative of v_O taking O to be fixed in the body. The two accelerations are related by

$$\mathbf{a}' = \mathbf{a} + \left(\frac{\mathbf{0}}{\omega \times v_O}\right). \quad (3.21)$$

If \mathbf{r} is a position vector giving the position of the body-fixed point at O relative to any fixed point, then

$$\begin{aligned} \mathbf{v}_O &= \dot{\mathbf{r}}, \\ \dot{\mathbf{v}}'_O &= \ddot{\mathbf{r}}, \\ \dot{\mathbf{v}}_O &= \ddot{\mathbf{r}} - \omega \times \mathbf{v}_O. \end{aligned} \quad (3.22)$$

The practical difference is that spatial accelerations are easier to use. For example, if the bodies B_1 and B_2 have velocities of \mathbf{v}_1 and \mathbf{v}_2 , respectively, and \mathbf{v}_{rel} is the relative velocity of B_2 with respect to B_1 , then

$$\mathbf{v}_2 = \mathbf{v}_1 + \mathbf{v}_{\text{rel}}.$$

The relationship between their spatial accelerations is obtained simply by differentiating the velocity formula

$$\frac{d}{dt}(\mathbf{v}_2 = \mathbf{v}_1 + \mathbf{v}_{\text{rel}}) \Rightarrow \mathbf{a}_2 = \mathbf{a}_1 + \mathbf{a}_{\text{rel}}.$$

Observe that spatial accelerations are composed by addition, exactly like velocities. There are no Coriolis or centrifugal terms to worry about. This is a significant improvement on the formulae for composing classical accelerations, such as those in [3.2, 13, 14].

3.2.10 Spatial Momentum

Suppose that a rigid body has a mass of m , a center of mass at C , and a rotational inertia of \bar{I}^{cm} about C (Fig. 3.2). If this body is moving with a spatial velocity of $\mathbf{v}_C = (\omega^T \underline{v}_C^T)^T$, then its linear momentum is $\mathbf{h} = m\mathbf{v}_C$, and its intrinsic angular momentum is $\mathbf{h}_C = \bar{I}^{\text{cm}}\omega$. Its moment of momentum about a general point, O , is $\mathbf{h}_O = \mathbf{h}_C + \mathbf{c} \times \mathbf{h}$, where $\mathbf{c} = \overrightarrow{OC}$. We can assemble these vectors into a spatial momentum vector as follows

$$\underline{\mathbf{h}}_C = \begin{pmatrix} \mathbf{h}_C \\ \mathbf{h} \end{pmatrix} = \begin{pmatrix} \bar{I}^{\text{cm}}\omega \\ m\underline{v}_C \end{pmatrix} \quad (3.23)$$

and

$$\underline{\mathbf{h}}_O = \begin{pmatrix} \mathbf{h}_O \\ \mathbf{h} \end{pmatrix} = \begin{pmatrix} \mathbf{1} & S(\mathbf{c}) \\ \mathbf{0} & \mathbf{1} \end{pmatrix} \underline{\mathbf{h}}_C. \quad (3.24)$$

Spatial momentum is a force vector, and transforms accordingly.

3.2.11 Spatial Inertia

The spatial momentum of a rigid body is the product of its spatial inertia and velocity

$$\mathbf{h} = I\mathbf{v}, \quad (3.25)$$

where \mathbf{I} is the spatial inertia. Expressed in Plücker coordinates at C , we have

$$\mathbf{h}_C = \mathbf{I}_C \mathbf{v}_C, \quad (3.26)$$

which implies

$$\mathbf{I}_C = \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix}. \quad (3.27)$$

This is the general formula for the spatial inertia of a rigid body expressed at its center of mass. To express it at another point, O , we proceed as follows. From (3.24), (3.26), and (3.27)

$$\begin{aligned} \mathbf{h}_O &= \begin{pmatrix} \mathbf{1} & S(\underline{c}) \\ \mathbf{0} & \mathbf{1} \end{pmatrix} \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \mathbf{v}_C \\ &= \begin{pmatrix} \mathbf{1} & S(\underline{c}) \\ \mathbf{0} & \mathbf{1} \end{pmatrix} \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \begin{pmatrix} \mathbf{1} & \mathbf{0} \\ S(\underline{c})^T & \mathbf{1} \end{pmatrix} \mathbf{v}_O \\ &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} + mS(\underline{c})S(\underline{c})^T & mS(\underline{c}) \\ mS(\underline{c})^T & m\mathbf{1} \end{pmatrix} \mathbf{v}_O; \end{aligned}$$

but we also have that $\mathbf{h}_O = \mathbf{I}_O \mathbf{v}_O$, so

$$\mathbf{I}_O = \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} + mS(\underline{c})S(\underline{c})^T & mS(\underline{c}) \\ mS(\underline{c})^T & m\mathbf{1} \end{pmatrix}. \quad (3.28)$$

This equation can also be written

$$\mathbf{I}_O = \begin{pmatrix} \bar{\mathbf{I}}_O & mS(\underline{c}) \\ mS(\underline{c})^T & m\mathbf{1} \end{pmatrix}, \quad (3.29)$$

where

$$\bar{\mathbf{I}}_O = \bar{\mathbf{I}}^{\text{cm}} + mS(\underline{c})S(\underline{c})^T \quad (3.30)$$

is the rotational inertia of the rigid body about O .

Spatial inertia matrices are symmetric and positive-definite. In the general case, 21 numbers are required

to specify a spatial inertia (e.g., for an articulated-body or operational-space inertia); but a rigid-body inertia needs only 10 parameters: the mass, the coordinates of the center of mass, and the six independent elements of either $\bar{\mathbf{I}}^{\text{cm}}$ or $\bar{\mathbf{I}}_O$.

The transformation rule for spatial inertias is

$$\mathbf{I}_B = {}^B\mathbf{X}_A^F \mathbf{I}_A^A \mathbf{X}_B, \quad (3.31)$$

where A and B are any two coordinate systems. In practice, we often need to calculate \mathbf{I}_A from \mathbf{I}_B , given only ${}^B\mathbf{X}_A$. The formula for this transformation is

$$\mathbf{I}_A = ({}^B\mathbf{X}_A)^T \mathbf{I}_B {}^B\mathbf{X}_A. \quad (3.32)$$

If two bodies, having inertias \mathbf{I}_1 and \mathbf{I}_2 , are rigidly connected to form a single composite body, then the inertia of the composite, \mathbf{I}_{tot} , is the sum of the inertias of its parts

$$\mathbf{I}_{\text{tot}} = \mathbf{I}_1 + \mathbf{I}_2. \quad (3.33)$$

This single equation takes the place of three equations in the traditional 3-D vector approach: one to compute the composite mass, one to compute the composite center of mass, and one to compute the composite rotational inertia. If a rigid body with inertia \mathbf{I} is moving with a velocity of \mathbf{v} , then its kinetic energy is

$$T = \frac{1}{2} \mathbf{v} \cdot \mathbf{I} \mathbf{v}. \quad (3.34)$$

If a rigid body, B , is part of a larger system, then it is possible to define an apparent-inertia matrix for B , which describes the relationship between a force acting on B and its resulting acceleration, taking into account the effects of the other bodies in the system. Such quantities are called articulated-body inertias. If B happens to be the end-effector of a robot, then its apparent inertia is called an operational-space inertia.

3.2.12 Equation of Motion

The spatial equation of motion states that the net force acting on a rigid body equals its rate of change of momentum

$$\mathbf{f} = \frac{d}{dt}(\mathbf{I}\mathbf{v}) = \mathbf{I}\mathbf{a} + \dot{\mathbf{I}}\mathbf{v}.$$

It can be shown that the expression $\dot{\mathbf{I}}\mathbf{v}$ evaluates to $(\mathbf{v} \times \mathbf{I}\mathbf{v})$ [3.8, 15], so the equation of motion can be written

$$\mathbf{f} = \mathbf{I}\mathbf{a} + \mathbf{v} \times \mathbf{I}\mathbf{v}. \quad (3.35)$$

This single equation incorporates both Newton's and Euler's equations of motion for a rigid body. To

Fig. 3.2 Spatial momentum

Table 3.1 Summary of spatial vector notation

Spatial quantities:	
\mathbf{v}	Velocity of a rigid body
\mathbf{a}	Spatial acceleration of a rigid body ($\mathbf{a} = \dot{\mathbf{v}}$)
\mathbf{a}'	Classical description of rigid-body acceleration expressed as a 6-D vector
\mathbf{f}	Force acting on a rigid body
\mathbf{I}	Inertia of a rigid body
\mathbf{X}	Plücker coordinate transform for motion vectors
\mathbf{X}^F	Plücker coordinate transform for force vectors ($\mathbf{X}^F = \mathbf{X}^{-T}$)
${}^B\mathbf{X}_A$	Plücker transform from A coordinates to B coordinates
\mathbf{m}	A generic motion vector (any element of \mathbf{M}^6)
3-D quantities:	
O	Coordinate system origin
\mathbf{r}	Position of the body-fixed point at O relative to any fixed point in space
$\boldsymbol{\omega}$	Angular velocity of a rigid body
\mathbf{v}_O	Linear velocity of the body-fixed point at O ($\mathbf{v}_O = \dot{\mathbf{r}}$)
$\dot{\boldsymbol{\omega}}$	Angular acceleration of a rigid body
$\dot{\mathbf{v}}_O$	The derivative of \mathbf{v}_O taking O to be fixed in space
$\dot{\mathbf{v}}'_O$	The derivative of \mathbf{v}_O taking O to be fixed in the body; the classical acceleration of the body-fixed point at O ($\dot{\mathbf{v}}'_O = \ddot{\mathbf{r}}$)
\mathbf{f}	Linear force acting on a rigid body, or the resultant of a system of linear forces
\mathbf{n}_O	Moment about O of a linear force or system of linear forces
m	Mass of a rigid body
\mathbf{c}	Position of a rigid body's center of mass, measured relative to O
\mathbf{h}	First moment of mass of a rigid body, $\mathbf{h} = m\mathbf{c}$; can also denote linear momentum
$\bar{\mathbf{I}}^{\text{cm}}$	Moment of inertia about a body's centre of mass
$\bar{\mathbf{I}}$	Moment of inertia about O
${}^B\mathbf{R}_A$	Orthonormal rotation matrix transforming from A coordinates to B coordinates
${}^A\mathbf{p}_B$	Location of the origin of B coordinates relative to the origin of A coordinates, expressed in A coordinates

verify this, we can recover them as follows. Expressing (3.35) at the body's center of mass, and using (3.16), (3.14), and (3.22), we have

$$\begin{aligned}
 \begin{pmatrix} \mathbf{n}_C \\ \mathbf{f} \end{pmatrix} &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \begin{pmatrix} \dot{\boldsymbol{\omega}} \\ \dot{\mathbf{v}}_C \end{pmatrix} - \begin{pmatrix} S(\boldsymbol{\omega})^T & S(\mathbf{v}_C)^T \\ \mathbf{0} & S(\boldsymbol{\omega})^T \end{pmatrix} \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} \boldsymbol{\omega} \\ m\mathbf{v}_C \end{pmatrix} \\
 &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \begin{pmatrix} \ddot{\boldsymbol{\omega}} \\ \ddot{\mathbf{v}}_C - \boldsymbol{\omega} \times \mathbf{v}_C \end{pmatrix} + \begin{pmatrix} \boldsymbol{\omega} \times \bar{\mathbf{I}}^{\text{cm}} \boldsymbol{\omega} \\ m\boldsymbol{\omega} \times \mathbf{v}_C \end{pmatrix} \\
 &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} \ddot{\boldsymbol{\omega}} + \boldsymbol{\omega} \times \bar{\mathbf{I}}^{\text{cm}} \boldsymbol{\omega} \\ m\ddot{\mathbf{v}}_C \end{pmatrix}.
 \end{aligned}$$

(3.36)

For meaning of $X^T I X$ see (3.32)			

3.2.13 Computer Implementation

The easiest way to implement spatial vector arithmetic on a computer is to start with an existing matrix arithmetic tool, like MATLAB and write (or download from the Web) routines to do the following:

1. Calculate $S(\mathbf{m})$ from \mathbf{m} according to (3.14).
2. Compose X from R and p according to (3.9).
3. Compose I from m , c , and \bar{I}^{cm} according to (3.28).

All other spatial arithmetic operations can be performed using standard matrix arithmetic routines. However, some additional routines could usefully be added to this list, such as:

- Routines to calculate R from various other representations of rotation.
- Routines to convert between spatial and 4×4 matrix quantities.

This is the recommended approach whenever human productivity is more important than computational efficiency. A software package along these lines can be found at [3.16].

If greater efficiency is required, then a more elaborate spatial arithmetic library must be used, in which

1. A dedicated data structure is defined for each kind of spatial quantity, and
2. A suite of calculation routines are provided, each implementing a spatial arithmetic operation by means of an efficient formula.

Some examples of suitable data structures and efficient formulae are shown in Table 3.1. Observe that the suggested data structures for rigid-body inertias and Plücker transforms contain only a third as many

numbers as the 6×6 matrices they represent. The efficient arithmetic formulae listed in this table offer cost savings ranging from a factor of 1.5 to a factor of 6 relative to the use of general 6×6 and 6×1 matrix arithmetic. Even more efficient formulae can be found in [3.17].

3.2.14 Summary

Spatial vectors are **6-D** vectors that combine the linear and angular aspects of rigid-body motion, resulting in a compact notation that is very suitable for describing dynamics algorithms. To avoid a few name clashes with **3-D** vectors, we have used bold upright letters to denote spatial vectors, while tensors are still denoted by italics. In the sections that follow, upright letters will be used to denote both spatial vectors and vectors that are concatenations of other vectors, like $\dot{\mathbf{q}}$.

Table 3.1 presents a summary of the spatial quantities and operators introduced in this section, together with the formulae that define them in terms of **3-D** quantities and operators. It also presents data structures and formulae for efficient computer implementation of spatial arithmetic. This table should be read in conjunction with Tables 2.5 and 2.6, which show how to compute the orientation, position, and spatial velocities for a variety of joint types. Note that iR_i and ${}^i p_i$ in these tables correspond to ${}^B R_A^T$ and ${}^A p_B$, respectively, when read in conjunction with Table 3.1.

3.3 Canonical Equations

The equations of motion of a robot mechanism are usually presented in one of two canonical forms: the joint-space formulation,

$$H(\mathbf{q})\ddot{\mathbf{q}} + C(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \tau_g(\mathbf{q}) = \boldsymbol{\tau}, \quad (3.37)$$

or the operational-space formulation,

$$A(\mathbf{x})\dot{\mathbf{v}} + \boldsymbol{\mu}(\mathbf{x}, \mathbf{v}) + \boldsymbol{\rho}(\mathbf{x}) = \mathbf{f}. \quad (3.38)$$

These equations show the functional dependencies explicitly: H is a function of \mathbf{q} , A is a function of \mathbf{x} , and so on. Once these dependencies are understood, they are usually omitted. In (3.38), \mathbf{x} is a vector of operational-space coordinates, while \mathbf{v} and \mathbf{f} are spatial vectors denoting the velocity of the end-effector and the external force acting on it. If the robot is redundant, then the coefficients of this equation must be defined as functions of \mathbf{q} and $\dot{\mathbf{q}}$ rather than \mathbf{x} and \mathbf{v} .

These two equations are further explained below, along with a description of the Lagrange formulation

of (3.37), and the impulsive equations of motion for impact.

3.3.1 Joint-Space Formulation

The symbols \mathbf{q} , $\dot{\mathbf{q}}$, $\ddot{\mathbf{q}}$, and $\boldsymbol{\tau}$ denote n -dimensional vectors of joint position, velocity, acceleration and force variables, respectively, where n is the number of degrees of motion freedom of the robot mechanism. H is an $n \times n$ symmetric, positive-definite matrix, and is called the generalized, or joint-space, inertia matrix (**JSIM**). C is an $n \times n$ matrix such that $C\dot{\mathbf{q}}$ is the vector of Coriolis and centrifugal terms (collectively known as *velocity product* terms); and τ_g is the vector of gravity terms. More terms can be added to this equation, as required, to account for other dynamical effects (e.g., viscous friction). The effects of a force \mathbf{f} exerted on the mechanism at the end-effector can be accounted for by adding the term $J^T \mathbf{f}$ to the right side of (3.37), where J is the Jacobian of the end-effector (Sect. 2.8.1).

\mathbf{q} specifies the coordinates of a point in the mechanism's configuration space. If the mechanism is a kinematic tree (Sect. 3.4), then \mathbf{q} contains every joint variable in the mechanism, otherwise it contains only an independent subset. The elements of \mathbf{q} are generalized coordinates. Likewise, the elements of $\dot{\mathbf{q}}$, $\ddot{\mathbf{q}}$, and $\boldsymbol{\tau}$ are generalized velocities, accelerations, and forces.

3.3.2 Lagrange Formulation

Various methods exist for deriving the terms in (3.37). The two that are most commonly used in robotics are the Newton–Euler formulation and the Lagrange formulation. The former works directly with Newton's and Euler's equations for a rigid body, which are contained within the spatial equation of motion, (3.35). This formulation is especially amenable to the development of efficient recursive algorithms for dynamics computations, such as those described in Sects. 3.5 and 3.6.

The Lagrange formulation proceeds via the Lagrangian of the robot mechanism,

$$L = T - U, \quad (3.39)$$

where T and U are the total kinetic and potential energy, respectively, of the mechanism. The kinetic energy is given by

$$T = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{H} \dot{\mathbf{q}}. \quad (3.40)$$

The dynamic equations of motion can then be developed using Lagrange's equation for each generalized coordinate

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = \tau_i. \quad (3.41)$$

The resulting equation can be written in scalar form

$$\sum_{j=1}^n H_{ij} \ddot{q}_j + \sum_{j=1}^n \sum_{k=1}^n C_{ijk} \dot{q}_j \dot{q}_k + \tau_{gi} = \tau_i, \quad (3.42)$$

which shows the structure of the velocity-product terms. C_{ijk} are known as Christoffel symbols of the first type, and are given by

$$C_{ijk} = \frac{1}{2} \left(\frac{\partial H_{ij}}{\partial q_k} + \frac{\partial H_{ik}}{\partial q_j} - \frac{\partial H_{jk}}{\partial q_i} \right). \quad (3.43)$$

They are functions of only the position variables, q_i . The elements of \mathbf{C} in (3.37) can be defined as

$$C_{ij} = \sum_{k=1}^n C_{ijk} \dot{q}_k. \quad (3.44)$$

However, \mathbf{C} is not unique, and other definitions are possible.

With the choice of \mathbf{C} given in (3.44), it is possible to show that the matrix \mathbf{N} , given by

$$\mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) = \dot{\mathbf{H}}(\mathbf{q}) - 2\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}), \quad (3.45)$$

is skew-symmetric [3.18]. Thus, for any $n \times 1$ vector $\boldsymbol{\alpha}$,

$$\boldsymbol{\alpha}^T \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) \boldsymbol{\alpha} = 0. \quad (3.46)$$

This property is quite useful in control, especially when considering $\boldsymbol{\alpha} = \dot{\mathbf{q}}$, which gives

$$\dot{\mathbf{q}}^T \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} = 0. \quad (3.47)$$

By applying the principle of conservation of energy, it can be shown that (3.47) holds for any choice of the matrix \mathbf{C} [3.18, 19].

3.3.3 Operational-Space Formulation

In (3.38), \mathbf{x} is a 6-D vector of operational-space coordinates giving the position and orientation of the robot's end-effector; \mathbf{v} is the velocity of the end-effector; and \mathbf{f} is the force exerted on the end-effector. \mathbf{x} is typically a list of Cartesian coordinates, and Euler angles or quaternion components, and is related to \mathbf{v} via a differential equation of the form

$$\dot{\mathbf{x}} = \mathbf{E}(\mathbf{x}) \mathbf{v}. \quad (3.48)$$

\mathbf{A} is the operational-space inertia matrix, which is the apparent inertia of the end-effector taking into account the effect of the rest of the robot's mechanism (i.e., it is an articulated-body inertia). $\boldsymbol{\mu}$ and $\boldsymbol{\rho}$ are vectors of velocity-product and gravity terms, respectively.

Operational space (also known as task space) is the space in which high-level motion and force commands are issued and executed. The operational-space formulation is therefore particularly useful in the context of motion and force control systems (Sects. 8.2 and 9.2). Equation (3.38) can be generalized to operational spaces with dimensions other than six, and to operational spaces that incorporate the motions of more than one end-effector [3.20].

The terms in (3.37) and (3.38) are related by the following formulae

$$\mathbf{v} = \mathbf{J} \dot{\mathbf{q}}, \quad (3.49)$$

$$\dot{\mathbf{v}} = \mathbf{J} \ddot{\mathbf{q}} + \dot{\mathbf{J}} \dot{\mathbf{q}}, \quad (3.50)$$

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{f}, \quad (3.51)$$

$$\mathbf{A} = (\mathbf{J} \mathbf{H}^{-1} \mathbf{J}^T)^{-1}, \quad (3.52)$$

$$\boldsymbol{\mu} = \mathbf{A} (\mathbf{J} \mathbf{H}^{-1} \mathbf{C} \dot{\mathbf{q}} - \dot{\mathbf{J}} \dot{\mathbf{q}}), \quad (3.53)$$

and

$$\boldsymbol{\rho} = \mathbf{A} \mathbf{J} \mathbf{H}^{-1} \boldsymbol{\tau}_g. \quad (3.54)$$

These equations assume that $m \leq n$ (m is the dimension of operational-space coordinates), and that the Jacobian \mathbf{J} has full rank. More details can be found in [3.21].

3.3.4 Impact Model

If a robot strikes a rigid body in its environment, then an impulsive force arises at the moment of impact and causes a step change in the robot's velocity. Let us assume that the impact occurs between the end effector and a rigid body in the environment, and that a spatial impulse of \mathbf{f}' is exerted on the end-effector. This impulse causes a step change of $\Delta \mathbf{v}$ in the end-effector's velocity; and the two are related by the operational-space equation of impulsive motion [3.22],

$$\mathbf{A} \Delta \mathbf{v} = \mathbf{f}' . \quad (3.55)$$

In joint space, the equation of impulsive motion for a robot mechanism is

$$\mathbf{H} \Delta \dot{\mathbf{q}} = \boldsymbol{\tau}' , \quad (3.56)$$

where $\boldsymbol{\tau}'$ and $\Delta \dot{\mathbf{q}}$ denote the joint-space impulse and velocity change, respectively. In the case of a collision

involving the robot's end-effector, we have

$$\boldsymbol{\tau}' = \mathbf{J}^T \mathbf{f}' \quad (3.57)$$

and

$$\Delta \mathbf{v} = \mathbf{J} \Delta \dot{\mathbf{q}} , \quad (3.58)$$

which follow from (3.51) and (3.49). Equations (3.55)–(3.57) imply that

$$\Delta \dot{\mathbf{q}} = \bar{\mathbf{J}} \Delta \mathbf{v} , \quad (3.59)$$

where $\bar{\mathbf{J}}$ is the inertia-weighted pseudoinverse of \mathbf{J} and is given by

$$\bar{\mathbf{J}} = \mathbf{H}^{-1} \mathbf{J}^T \mathbf{A} . \quad (3.60)$$

$\bar{\mathbf{J}}$ is also known as the dynamically consistent generalized inverse of the Jacobian matrix [3.21]. Note that the expression $\mathbf{A} \mathbf{J} \mathbf{H}^{-1}$, which appears in (3.53) and (3.54), is equal to $\bar{\mathbf{J}}^T$ since \mathbf{H} and \mathbf{A} are both symmetric. Although we have introduced $\bar{\mathbf{J}}$ in the context of impulsive dynamics, it is more typically used in normal (i. e., non-impulsive) dynamics equations.

3.4 Dynamic Models of Rigid-Body Systems

A basic rigid-body model of a robot mechanism has four components: a connectivity graph, link and joint geometry parameters, link inertia parameters, and a set of joint models. To this model, one can add various force-producing elements, such as springs, dampers, joint friction, actuators, and drives. The actuators and drives, in particular, may have quite elaborate dynamic models of their own. It is also possible to add extra motion freedoms to model elasticity in the joint bearings or links (Chap. 11). This section describes a basic model. More on this topic can be found in books such as [3.3, 8, 23].

3.4.1 Connectivity

A connectivity graph is an undirected graph in which each node represents a rigid body and each arc represents a joint. The graph must be connected; and exactly one node represents a fixed base or reference frame. If the graph represents a mobile robot (i. e., a robot that is not connected to a fixed base), then it is necessary to introduce a fictitious 6-DOF joint between the fixed base and any one body in the mobile robot. The chosen body is then known as a *floating base*. If a single graph

is to represent a collection of mobile robots, then each robot has its own floating base, and each floating base has its own 6-DOF joint. Note that a 6-DOF joint imposes no constraints on the two bodies it connects, so the introduction of a 6-DOF joint alters the connectivity of the graph without altering the physical properties of the system it represents.

In graph-theory terminology, a loop is an arc that connects a node to itself, and a cycle is a closed path that does not traverse any arc more than once. In the connectivity graph of a robot mechanism, loops are not allowed, and cycles are called kinematic loops. A mechanism that contains kinematic loops is called a closed-loop mechanism; and a mechanism that does not is called an open-loop mechanism or a kinematic tree. Every closed-loop mechanism has a spanning tree, which defines an open-loop mechanism, and every joint that is not in the spanning tree is called a loop-closing joint. The joints in the tree are called tree joints.

The fixed base serves as the root node of a kinematic tree, and the root node of any spanning tree on a closed-loop mechanism. A kinematic tree is said to be branched if at least one node has at least two children, and unbranched otherwise. An unbranched kinematic

tree is also called a kinematic chain, and a branched tree can be called a branched kinematic chain. A typical industrial robot arm, without a gripper, is a kinematic chain, while a typical humanoid robot is a kinematic tree with a floating base.

In a system containing N_B moving bodies and N_J joints, where N_J includes the 6-DOF joints mentioned above, the bodies and joints are numbered as follows. First, the fixed base is numbered body 0. The other bodies are then numbered from 1 to N_B in any order such that each body has a higher number than its parent. If the system contains kinematic loops then one must first choose a spanning tree, and commit to that choice, since the identity of a body's parent is determined by the spanning tree. This style of numbering is called a *regular numbering scheme*.

Having numbered the bodies, we number the tree joints from 1 to N_B such that joint i connects body i to its parent. The loop-closing joints, if any, are then numbered from $N_B + 1$ to N_J in any order. Each loop-closing joint k closes one independent kinematic loop, and we number the loops from 1 to N_L (where $N_L = N_J - N_B$ is the number of independent loops) such that loop l is the one closed by joint $k = N_B + l$. Kinematic loop l is the unique cycle in the graph that traverses joint k , but does not traverse any other loop-closing joint.

For an unbranched kinematic tree, these rules produce a unique numbering in which the bodies are numbered consecutively from base to tip, and the joints are numbered such that joint i connects bodies i and $i - 1$. In all other cases, regular numberings are not unique.

Although the connectivity graph is undirected, it is necessary to assign a direction to each joint for the purpose of defining joint velocity and force. This is necessary for both tree joints and loop-closing joints. Specifically, a joint is said to connect from one body to another. We may call them the predecessor $p(i)$ and successor $s(i)$ for joint i , respectively. Joint velocity is then defined as the velocity of the successor relative to the predecessor; and joint force is defined as a force acting on the successor. It is standard practice (but not a necessity) for all tree joints to connect from the parent to the child.

The connectivity of a kinematic tree, or the spanning tree on a closed-loop mechanism, is described by an N_B -element array of parent body numbers, where the i -th element $p(i)$ is the parent of body i . Note that the parent $p(i)$ for body i is also the predecessor $p(i)$ for joint i , and thus the common notation. Many algorithms rely on the property $p(i) < i$ to perform their calculations in the correct order. The set of all body numbers for the children of body i , $c(i)$, is also useful in many recursive algorithms.

The connectivity data for kinematic loops may be described in a variety of ways. A representation that facilitates use in recursive algorithms includes the following conventions. Loop-closing joint k joins bodies $p(k)$ (the predecessor) and $s(k)$ (the successor). The set $LR(i)$ for body i gives the numbers of the loops for which body i is the root. Using the property $p(i) < i$ for bodies in the spanning tree, the root of a loop is chosen as the body with the lowest number. In addition, the set $LB(i)$ for body i gives the numbers of the loops to which body i belongs but is not the root.

An example of a closed-loop system is given in Fig. 3.3. The system consists of a humanoid mechanism with topologically varying contacts, with the environment and within the mechanism, which form closed loops. The system has $N_B = 16$ moving bodies and $N_J = 19$ joints with $N_L = N_J - N_B = 3$ loops. The main body (1) is considered to be a *floating base* for this mobile robot system. It is connected to the fixed base (0) through a fictitious 6-DOF joint (1). To complete the example, the loop-closing joint and the body numbers $p(k)$ and $s(k)$ as well as the root body for each loop are given in Table 3.2. The body-based sets $c(i)$ and

Fig. 3.3 Humanoid robot example. Note: to distinguish between body numbers and joint numbers in this figure, body numbers are preceded by a B for clarity

$LB(i)$ are given in Table 3.3. Note that $LR(0) = \{1, 3\}$ and $LR(1) = \{2\}$ and all other LR sets are null for this example.

3.4.2 Link Geometry

When two bodies are connected by a joint, a complete description of the connection consists of a description of the joint itself, and the locations of two coordinate frames, one in each body, which specify where in each body the joint is located. If there are N_J joints in the system, then there are a total of $2N_J$ joint-attachment frames. One half of these frames are identified with the numbers 1 to N_J , and the remainder with the labels $J1$ to JN_J . Each joint i connects from frame Ji to frame i .

For joints 1 to N_B (i.e., the tree joints), frame i is rigidly attached to body i . For joints $N_B + 1$ to N_J , frame k for loop-closing joint k will be rigidly attached to body $s(k)$. The second coordinate frame Ji is attached to the predecessor $p(i)$ for each joint i , whether it is a tree joint or a loop-closing joint. Coordinate frame Ji provides a base frame for joint i in that the joint rotation and/or translation is defined relative to this frame.

Figure 3.4 shows the coordinate frames and transforms associated with each joint in the system. The overall transform from frame $p(i)$ coordinates to frame i coordinates for a tree joint is given by

$${}^iX_{p(i)} = {}^iX_{Ji} {}^{Ji}X_{p(i)} = X_J(i)X_L(i). \quad (3.61)$$

The transform $X_L(i)$ is a fixed link transform which sets the base frame Ji of joint i relative to $p(i)$. It may be used to transform spatial motion vectors from $p(i)$ to Ji coordinates. The transform $X_J(i)$ is a variable joint

Table 3.2 Loop-closing joints and roots of loops for the humanoid example

8					

Fig. 3.4a,b Coordinate frames and transforms associated with (a) a tree joint and (b) a loop-closing joint

transform which completes the transformation across joint i from Ji to i coordinates.

Similarly, the overall transform from frame $p(k)$ coordinates to frame k coordinates for a loop-closing joint is given by

$${}^kX_{p(k)} = {}^kX_{Jk} {}^{Jk}X_{p(k)} = X_J(k)X_{L1}(k). \quad (3.62)$$

An additional transform $X_{L2}(k)$ is defined from frame $s(k)$ coordinates to frame k coordinates and is given by

$$X_{L2}(k) = {}^kX_{s(k)}. \quad (3.63)$$

Link and joint geometry data can be specified in a variety of different ways. The most common method is to use *Denavit–Hartenberg* parameters [3.24]. However, standard Denavit–Hartenberg parameters are not completely general, and are insufficient for describing the geometry for a branched kinematic tree, or for a mechanism containing certain kinds of multi-DOF joints. A modified form of Denavit–Hartenberg parameters [3.2] is used for single-DOF joints in this Handbook (Sect. 2.4). The parameters have been extended for branched kinematic trees [3.23] and closed-loop mechanisms.

3.4.3 Link Inertias

The link inertia data consists of the masses, positions of centers of mass, and rotational inertias of each link in the mechanism. The inertia parameters for link i are expressed in coordinate frame i , and are therefore constants.

3.4.4 Joint Models

The relationship between connected links is described using the general joint model of *Roberson and Schwertassek* [3.3]. For a kinematic tree or spanning tree on

a closed-loop mechanism, an $n_i \times 1$ vector, $\dot{\mathbf{q}}_i$, relates the velocity of link i to the velocity of its parent, link $p(i)$, where n_i is the number of degrees of freedom at the joint connecting the two links. For a loop-closing joint in a closed-loop mechanism, the relationship is between the velocity of link $s(i)$ (the successor) and the velocity of link $p(i)$ (the predecessor). In either case, the relationship is between the velocity of coordinate frames i and Ji .

Let \mathbf{v}_{rel} and \mathbf{a}_{rel} denote the velocity and acceleration across joint i , that is, the velocity and acceleration of link $s(i)$ relative to $p(i)$. The free modes of the joint are represented by the $6 \times n_i$ matrix Φ_i , such that \mathbf{v}_{rel} and \mathbf{a}_{rel} are given as follows

$$\mathbf{v}_{\text{rel}} = \Phi_i \dot{\mathbf{q}}_i \quad (3.64)$$

and

$$\mathbf{a}_{\text{rel}} = \Phi_i \ddot{\mathbf{q}}_i + \dot{\Phi}_i \dot{\mathbf{q}}_i, \quad (3.65)$$

where Φ_i and $\dot{\Phi}_i$ depend on the type of joint [3.3]. The matrix Φ_i has full column rank, so we can define a complementary matrix, Φ_i^c , such that the 6×6 matrix $(\Phi_i \Phi_i^c)$ is invertible. We can regard the columns of this matrix as forming a basis on M^6 such that the first n_i basis vectors define the directions in which motion is allowed, and the remaining $6 - n_i = n_i^c$ vectors define directions in which motion is not allowed. Thus, Φ_i^c represents the constrained modes of joint i .

The force transmitted across joint i from its predecessor to its successor, \mathbf{f}_i , is given as follows

$$\mathbf{f}_i = (\Psi_i \Psi_i^c) \begin{pmatrix} \boldsymbol{\tau}_i \\ \boldsymbol{\lambda}_i \end{pmatrix}, \quad (3.66)$$

where $\boldsymbol{\tau}_i$ is the $n_i \times 1$ vector of applied forces along the free modes, $\boldsymbol{\lambda}_i$ is the $(6 - n_i) \times 1$ vector of constraint forces, and Ψ_i and Ψ_i^c are computed as follows

$$(\Psi_i \Psi_i^c) = (\Phi_i \Phi_i^c)^{-T}. \quad (3.67)$$

For most common joint types, it is possible to choose Φ_i and Φ_i^c such that the matrix $(\Phi_i \Phi_i^c)$ is numerically orthonormal, so that $(\Psi_i \Psi_i^c)$ is numerically equal to $(\Phi_i \Phi_i^c)$. Note that (3.67) implies the following relationships: $(\Psi_i)^T \Phi_i = \mathbf{1}_{n_i \times n_i}$, $(\Psi_i)^T \Phi_i^c = \mathbf{0}_{n_i \times (6 - n_i)}$, $(\Psi_i^c)^T \Phi_i = \mathbf{0}_{(6 - n_i) \times n_i}$, and $(\Psi_i^c)^T \Phi_i^c = \mathbf{1}_{(6 - n_i) \times (6 - n_i)}$. When applied to (3.66), the following useful relationship results

$$\boldsymbol{\tau}_i = \Phi_i^T \mathbf{f}_i. \quad (3.68)$$

The value of $\dot{\Phi}_i$ in (3.65) depends on the type of joint. The general formula is

$$\dot{\Phi}_i = \dot{\Phi}_i + \mathbf{v}_i \times \Phi_i, \quad (3.69)$$

where \mathbf{v}_i is the velocity of link i , and $\dot{\Phi}_i$ is the apparent derivative of Φ_i , as seen by an observer moving with link i , and is given by

$$\dot{\Phi}_i = \frac{\partial \Phi_i}{\partial \mathbf{q}_i} \dot{\mathbf{q}}_i. \quad (3.70)$$

For most common joint types, $\dot{\Phi}_i = \mathbf{0}$.

Single-DOF joints ($n_i = 1$) are especially straightforward to work with when using the Denavit–Hartenberg convention. Motion is chosen along (prismatic) or about (revolute) the $\hat{\mathbf{z}}_i$ coordinate axis. In this case, $\Phi_i = (000001)^T$ for a prismatic joint and $\Phi_i = (001000)^T$ for a revolute joint. Also, $\dot{\Phi}_i = \mathbf{0}$.

The fictitious 6-DOF joint for a floating base for a mobile robot is also handled relatively easily. For this case, $\Phi_i = \mathbf{1}$ (6×6 identity matrix) and $\dot{\Phi}_i = \mathbf{0}$.

The revolute joint and floating-base joint, as well as the universal joint ($n_i = 2$) and spherical joint ($n_i = 3$) are illustrated in the example in the next section. For additional details on joint kinematics, see Sect. 2.3.

3.4.5 Example System

In order to illustrate the conventions used for the link and joint models, coordinate frames are attached to the first five links (bodies) and fixed base of the humanoid robot as shown in Fig. 3.5. Note that frame Ji is attached to link $p(i) = i - 1$ for each of the five joints. For this example, the origin of frame $J1$ is set coincident with the origin of frame 0, and the origins of frames $J2$, $J3$, $J4$, and $J5$ are coincident with the origins of frames 2, 3, 4, and 5, respectively.

Note that $J1$ could be set at any position/orientation on the fixed base (B0) to permit the most convenient

Table 3.4 Number of degrees of freedom (n_i), fixed rotation (${}^{Ji}R_{p(i)}$) and position (${}^{p(i)}p_{Ji}$) from frame $p(i)$ to base frame Ji for joint i of the example system. Note that $2l_i$ is the nominal length of link i along its long axis

Joint	n_i	${}^{Ji}R_{p(i)}$	${}^{p(i)}p_{Ji}$
1	6	$\mathbf{1}_{3 \times 3}$	$\mathbf{0}_{3 \times 1}$
2	1	$\mathbf{1}_{3 \times 3}$	$\begin{pmatrix} 0 \\ 0 \\ -l_1 \end{pmatrix}$
3	3	$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$	$\begin{pmatrix} 0 \\ -l_2 \\ 0 \end{pmatrix}$
4	1	$\mathbf{1}_{3 \times 3}$	$\begin{pmatrix} 0 \\ 2l_3 \\ 0 \end{pmatrix}$
5	2	$\begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$	$\begin{pmatrix} 0 \\ 2l_4 \\ 0 \end{pmatrix}$

Fig. 3.5 Coordinate frames for the first five links and joints of the humanoid robot example

representation for the motion of the floating base (B1) relative to the fixed base. Also, the origin of $J2$ could be set anywhere along \hat{z}_2 .

The number of degrees of freedom, and fixed rotation and position of the base frames Ji for each joint of the example system, are given in Table 3.4. The

rotation ${}^{Ji}R_{p(i)}$ transforms 3-D vectors in $p(i)$ coordinates to Ji coordinates. The position ${}^{p(i)}p_{Ji}$ is the vector giving the position of the origin O_{Ji} relative to $O_{p(i)}$, expressed in $p(i)$ coordinates. The spatial transform $X_L(i) = {}^{Ji}X_{p(i)}$ may be composed from these 3-D quantities through the equation for ${}^B X_A$ in Table 3.1. The humanoid has a floating base, the torso, a revolute joint between the torso and pelvis (about \hat{z}_2), a spherical joint at the hip, a revolute joint at the knee, and a universal joint at the ankle. As shown in Fig. 3.5, the leg is slightly bent and the foot is turned out to the side ($\approx 90^\circ$ rotation about \hat{y}_3 at the hip).

The free modes, velocity variables, and position variables for all of the joint types in the humanoid are given in Tables 2.5 and 2.6. The expressions for ${}^J R_i$ and ${}^J p_i$ in these tables give ${}^i R_{Ji}^T$ and ${}^{Ji} p_i$, respectively, through which the joint transform $X_J(i) = {}^i X_{Ji}$ may be composed. Revolute joints follow the Denavit–Hartenberg convention with rotation about the \hat{z}_i axis. The ankle has a pitch rotation of α_5 about the \hat{z}_{J5} axis followed by a roll rotation of β_5 about the \hat{y}_5 axis (see the Z–Y–X Euler angle definitions in Table 2.1). The hip is modeled as a ball-and-socket, spherical joint. To avoid the singularities that are associated with Euler angles, the quaternion ϵ_i may be used to represent the orientation at the hip. The relationship between the quaternion rate $\dot{\epsilon}_i$ and the relative rotation rate $\omega_{i\text{rel}}$ is given in (2.8) of the Handbook.

The floating base uses the position of the torso ${}^0 p_1$ and quaternion ϵ_1 for its position and orientation state variables, respectively. The position of the torso may be computed by integrating the velocity for the link, as expressed in fixed base coordinates: ${}^0 v_1 = {}^0 R_1 v_1$, where v_1 is the velocity of the torso in moving coordinates.

Note that $\dot{\phi}_i = 0$ for all joints except the universal joint. Since the components of \hat{z}_{J5} in link 5 coordinates vary with β_5 , $\dot{z}_{J5} \neq 0$. See Sect. 2.3 of the Handbook for further details of the joint kinematics.

3.5 Kinematic Trees

The dynamics of a kinematic tree is simpler, and easier to calculate, than the dynamics of a closed-loop mechanism. Indeed, many algorithms for closed-loop mechanisms work by first calculating the dynamics of a spanning tree, and then subjecting it to the loop-closure constraints.

This section describes the following dynamics algorithms for kinematic trees: the recursive Newton–Euler algorithm (RNEA) for inverse dynamics, the articulated-body algorithm (ABA) for forward dynamics, the composite-rigid-body algorithm (CRBA) for

calculating the joint-space inertia matrix (JSIM), and two algorithms to calculate the operational-space inertia matrix (OSIM). Implementations of the first three can be found in [3.16].

3.5.1 The Recursive Newton–Euler Algorithm

This is an $O(n)$ algorithm for calculating the inverse dynamics of a fixed-base kinematic tree, and is based on the very efficient RNEA of Luh et al. [3.4]. A floating-

base version can be found in [3.8, 15]. Given the joint position and velocity variables, this algorithm calculates the applied joint torque/force variables required to produce a given set of joint accelerations.

The link velocities and accelerations are first computed through an outward recursion from the fixed base to the leaf links of the tree. The required forces on each link are computed using the Newton–Euler equations (3.35) during this recursion. A second, inward recursion uses the force balance equations at each link to compute the spatial force across each joint and the value of each joint torque/force variable. The key step for computational efficiency is to refer most quantities to local link coordinates. Also, the effects of gravity on each link are efficiently included in the equations by accelerating the base of the mechanism upward.

The calculation proceeds in four steps, as follows, with two steps in each of the two recursions.

Step 1

Calculate the velocity and acceleration of each link in turn, starting with the known velocity and acceleration of the fixed base, and working towards the tips (i. e., the leaf nodes in the connectivity graph).

The velocity of each link in a kinematic tree is given by the recursive formula

$$\mathbf{v}_i = \mathbf{v}_{p(i)} + \boldsymbol{\Phi}_i \dot{\mathbf{q}}_i, \quad (\mathbf{v}_0 = \mathbf{0}), \quad (3.71)$$

where \mathbf{v}_i is the velocity of link i , $\boldsymbol{\Phi}_i$ is the motion matrix of joint i , and $\dot{\mathbf{q}}_i$ is the vector of joint velocity variables for joint i .

The equivalent formula for accelerations is obtained by differentiating (3.71), giving

$$\mathbf{a}_i = \mathbf{a}_{p(i)} + \boldsymbol{\Phi}_i \ddot{\mathbf{q}}_i + \dot{\boldsymbol{\Phi}}_i \dot{\mathbf{q}}_i, \quad (\mathbf{a}_0 = \mathbf{0}), \quad (3.72)$$

where \mathbf{a}_i is the acceleration of link i , and $\ddot{\mathbf{q}}_i$ is the vector of joint acceleration variables.

The effect of a uniform gravitational field on the mechanism can be simulated by initializing \mathbf{a}_0 to $-\mathbf{a}_g$ instead of zero, where \mathbf{a}_g is the gravitational acceleration vector. In this case, \mathbf{a}_i is not the true acceleration of link i , but the sum of its true acceleration and $-\mathbf{a}_g$.

Step 2

Calculate the equation of motion for each link. This step computes the forces required to cause the accelerations calculated in step 1. The equation of motion for link i is

$$\mathbf{f}_i^a = \mathbf{I}_i \mathbf{a}_i + \mathbf{v}_i \times \mathbf{I}_i \mathbf{v}_i, \quad (3.73)$$

where \mathbf{I}_i is the spatial inertia of link i , and \mathbf{f}_i^a is the net force acting on link i .

Fig. 3.6 Forces acting on link i

Step 3

Calculate the spatial force across each joint. Referring to Fig. 3.6, the net force acting on link i is

$$\mathbf{f}_i^a = \mathbf{f}_i^e + \mathbf{f}_i - \sum_{j \in c(i)} \mathbf{f}_j,$$

where \mathbf{f}_i is the force transmitted across joint i , \mathbf{f}_i^e is the sum of all relevant external forces acting on link i , and $c(i)$ is the set of children of link i . Rearranging this equation gives the following recursive formula for calculating the joint forces

$$\mathbf{f}_i = \mathbf{f}_i^a - \mathbf{f}_i^e + \sum_{j \in c(i)} \mathbf{f}_j, \quad (3.74)$$

where i iterates from N_B to 1.

\mathbf{f}_i^e may include contributions from springs, dampers, force fields, contact with the environment, and so on, but its value is assumed to be known, or at least to be calculable from known quantities.

If gravity has not been simulated by a fictitious base acceleration, then the gravitational force acting on link i must be included in \mathbf{f}_i^e .

Step 4

Calculate the joint force variables, $\boldsymbol{\tau}_i$. By definition, they are given by the equation

$$\boldsymbol{\tau}_i = \boldsymbol{\Phi}_i^T \mathbf{f}_i. \quad (3.75)$$

Coordinate-Free Algorithm

Equations (3.71)–(3.75) imply the algorithm shown in Algorithm 3.1, which is the coordinate-free version of the RNEA. This is the simplest form of the algorithm, and it is suitable for mathematical analysis and related purposes. However, it is not suitable for numerical

computation because a numerical version must use coordinate vectors.

Algorithm 3.1 *Coordinate-free recursive Newton–Euler algorithm (RNEA) for inverse dynamics*

```

v0 = 0
a0 = −ag
for i = 1 to NB do
  vi = vp(i) + Φi q̇i
  ai = ap(i) + Φi q̈i + Φ̇i q̇i
  fi = Ii ai + vi × Ii vi − fic
end for
for i = NB to 1 do
  τi = ΦiT fi
  if p(i) ≠ 0 then
    fp(i) = fp(i) + fi
  end if
end for

```

Link–Coordinates Algorithm

In general, we say that an algorithm is implemented in link coordinates if a coordinate system is defined for each link, and the calculations pertaining to link *i* are performed in the coordinate system associated with link *i*. The alternative is to implement the algorithm in absolute coordinates, in which case all calculations are performed in a single coordinate system, typically that of the base link. In practice, the RNEA is more computationally efficient when implemented in link coordinates, and the same is true of most other dynamics algorithms.

To convert the RNEA to link coordinates, we first examine the equations to see which ones involve quantities from more than one link. Equations (3.73) and (3.75) each involve quantities pertaining to link *i* only, and therefore need no modification. Such equations are said to be local to link *i*. The remaining equations involve quantities from more than one link, and therefore require the insertion of coordinate transformation matrices. The modified versions of (3.71), (3.72), and (3.74) are

$$\mathbf{v}_i = {}^iX_{p(i)} \mathbf{v}_{p(i)} + \Phi_i \dot{\mathbf{q}}_i, \quad (3.76)$$

$$\mathbf{a}_i = {}^iX_{p(i)} \mathbf{a}_{p(i)} + \Phi_i \ddot{\mathbf{q}}_i + \dot{\Phi}_i \dot{\mathbf{q}}_i, \quad (3.77)$$

and

$$\mathbf{f}_i = \mathbf{f}_i^a - {}^iX_0^F {}^0\mathbf{f}_i^c + \sum_{j \in c(i)} {}^iX_j^F \mathbf{f}_j. \quad (3.78)$$

Equation (3.78) assumes that external forces are expressed in absolute (i. e., link 0) coordinates.

Algorithm 3.2 *Recursive Newton–Euler algorithm using spatial vectors*

inputs: **q**, **q̇**, **q̈**, *model*, ⁰**f**_{*i*}^c
output: **τ**
model data : *N*_{*B*}, *jtype*(*i*), *p*(*i*), **X**_{*L*}(*i*), **I**_{*i*}

```

v0 = 0
a0 = −ag
for i = 1 to NB do
  XJ(i) = xjcalc(jtype(i), qi)
  iXp(i) = XJ(i) XL(i)
  if p(i) ≠ 0 then
    iX0 = iXp(i) p(i)X0
  end if
  Φi = pccalc(jtype(i), qi)
  Φ̇i = pdcalc(jtype(i), qi, q̇i)
  vi = iXp(i) vp(i) + Φi q̇i
  ξi = Φ̇i q̇i + vi × Φi q̇i
  ai = iXp(i) ap(i) + Φi q̈i + ξi
  fi = Ii ai + vi × Ii vi − iX0−T 0fic
end for
for i = NB to 1 do
  τi = ΦiT fi
  if p(i) ≠ 0 then
    fp(i) = fp(i) + iXp(i)T fi
  end if
end for

```

The complete algorithm is shown in Algorithm 3.2. The function *jtype* returns the type code for joint *i*; the function *xjcalc* calculates the joint transformation matrix for the specified type of joint; and the functions *pccalc* and *pdcalc* calculate **Φ**_{*i*} and **Φ̇**_{*i*}. The formulae used by these functions for a variety of joint types can be found in Tables 2.5 and 2.6, bearing in mind that the rotation matrices that must be used are the transposes of those listed in these tables. In the general case, both *pccalc* and *pdcalc* are needed. However, for most common joint types, **Φ**_{*i*} is a known constant in link coordinates, and **Φ̇**_{*i*} is therefore zero. If it is known in advance that all joints will have this property, then the algorithm can be simplified accordingly. The quantities **I**_{*i*} and **X**_{*L*}(*i*) are known constants in link coordinates, and are part of the data structure describing the robot mechanism.

The last assignment in the first loop initializes each **f**_{*i*} to the expression **f**_{*i*}^a − ^{*i*}**X**₀^F ⁰**f**_{*i*}^c (using the identity ^{*i*}**X**₀^F = ^{*i*}**X**₀^{−T}). The summation on the right-hand side of (3.78) is then performed in the second loop. This algorithm includes code to calculate ^{*i*}**X**₀, which is used to transform the external forces to link coordinates. If there are no external forces, then this code can be omitted. If there is only a single external force (e.g., a force

at the end-effector of a robot arm) then this code can be replaced with code that transforms the external force vector successively from one link coordinate system to the next, using ${}^iX_{p(i)}$.

Note: although the phrase *link coordinates* suggests that we are using moving coordinate frames, the algorithm is in fact implemented in stationary coordinates that happen to coincide with the moving coordinates at the current instant.

3-D Vector RNEA

The original version of the **RNEA** was developed and expressed using **3-D** vectors (e.g. [3.2, 4]). Algorithm 3.3 shows a special case of this algorithm, in which the joints are assumed to be revolute, and the joint axes are assumed to coincide with the z axes of the link coordinate systems. (Without these assumptions, the equations would be a lot longer.) It also assumes that the external forces are zero.

Algorithm 3.3 Recursive Newton–Euler algorithm in 3-D vectors, for revolute joints only

inputs: $\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \text{model}$
output: $\boldsymbol{\tau}$
model data : $N_B, p(i), \mathbf{R}_L(i), {}^{p(i)}\mathbf{p}_i, m_i, \mathbf{c}_i, \bar{\mathbf{I}}_i^{\text{cm}}$

```

 $\boldsymbol{\omega}_0 = \mathbf{0}$ 
 $\dot{\boldsymbol{\omega}}_0 = \mathbf{0}$ 
 $\dot{\mathbf{v}}'_0 = -\dot{\mathbf{v}}'_g$ 
for  $i = 1$  to  $N_B$  do
   ${}^i\mathbf{R}_{p(i)} = \text{rotz}(\mathbf{q}_i) \mathbf{R}_L(i)$ 
   $\boldsymbol{\omega}_i = {}^i\mathbf{R}_{p(i)} \boldsymbol{\omega}_{p(i)} + \hat{\mathbf{z}}_i \dot{\mathbf{q}}_i$ 
   $\dot{\boldsymbol{\omega}}_i = {}^i\mathbf{R}_{p(i)} \dot{\boldsymbol{\omega}}_{p(i)} + ({}^i\mathbf{R}_{p(i)} \boldsymbol{\omega}_{p(i)}) \times \hat{\mathbf{z}}_i \dot{\mathbf{q}}_i + \hat{\mathbf{z}}_i \ddot{\mathbf{q}}_i$ 
   $\dot{\mathbf{v}}'_i = {}^i\mathbf{R}_{p(i)} (\dot{\mathbf{v}}'_{p(i)} + \dot{\boldsymbol{\omega}}_{p(i)} \times {}^{p(i)}\mathbf{p}_i$ 
     $+ \boldsymbol{\omega}_{p(i)} \times \boldsymbol{\omega}_{p(i)} \times {}^{p(i)}\mathbf{p}_i)$ 
   $\mathbf{f}_i = m_i(\dot{\mathbf{v}}'_i + \dot{\boldsymbol{\omega}}_i \times \mathbf{c}_i + \boldsymbol{\omega}_i \times \boldsymbol{\omega}_i \times \mathbf{c}_i)$ 
   $\mathbf{n}_i = \bar{\mathbf{I}}_i^{\text{cm}} \dot{\boldsymbol{\omega}}_i + \boldsymbol{\omega}_i \times \bar{\mathbf{I}}_i^{\text{cm}} \boldsymbol{\omega}_i + \mathbf{c}_i \times \mathbf{f}_i$ 
end for
for  $i = N_B$  to  $1$  do
   $\boldsymbol{\tau}_i = \hat{\mathbf{z}}_i^T \mathbf{n}_i$ 
  if  $p(i) \neq 0$  then
     $\mathbf{f}_{p(i)} = \mathbf{f}_{p(i)} + {}^i\mathbf{R}_{p(i)}^T \mathbf{f}_i$ 
     $\mathbf{n}_{p(i)} = \mathbf{n}_{p(i)} + {}^i\mathbf{R}_{p(i)}^T \mathbf{n}_i + {}^{p(i)}\mathbf{p}_i \times {}^i\mathbf{R}_{p(i)}^T \mathbf{f}_i$ 
  end if
end for

```

In this algorithm, $\dot{\mathbf{v}}'_g$ is the linear acceleration due to gravity, expressed in base (link 0) coordinates; rotz computes the transpose of the matrix shown in (2.2); $\mathbf{R}_L(i)$ is the rotational component of $\mathbf{X}_L(i)$; ${}^i\mathbf{R}_{p(i)}$ is the rotational component of ${}^iX_{p(i)}$; pcalc and pdcalc are not used because $\dot{\boldsymbol{\Phi}}_i$ is the known constant $(\hat{\mathbf{z}}^T \mathbf{0}^T)^T$;

$\dot{\mathbf{v}}'_i$ is the linear acceleration of the origin of link i coordinates (O_i), and is the linear component of the classical acceleration of link i ; ${}^{p(i)}\mathbf{p}_i$ is the position of O_i relative to $O_{p(i)}$ expressed in $p(i)$ coordinates; and m_i, \mathbf{c}_i , and $\bar{\mathbf{I}}_i^{\text{cm}}$ are the inertia parameters of link i . (See Table 3.1 for the equations relating these **3-D** quantities to the corresponding spatial quantities.)

At first sight, the **3-D** vector algorithm looks significantly different from the spatial vector algorithm. Nevertheless, it can be obtained directly from the spatial vector algorithm simply by expanding the spatial vectors to their **3-D** components, restricting the joint type to revolute, converting spatial accelerations to classical accelerations (i.e., replacing each instance of $\dot{\mathbf{v}}_i$ with $\dot{\mathbf{v}}'_i - \boldsymbol{\omega}_i \times \mathbf{v}_i$ as per (3.22)), and applying some **3-D** vector identities to bring the equations into the form shown in the table. The conversion from spatial to classical acceleration has one interesting side-effect: \mathbf{v}_i cancels out of the equation of motion, and therefore does not need to be calculated. As a result, the **3-D** version of the algorithm has a slight speed advantage over the spatial version.

3.5.2 The Articulated-Body Algorithm

The **ABA** is an $O(N_B)$ algorithm for calculating the forward dynamics of a kinematic tree. However, under normal circumstances, $O(N_B) = O(n)$, so we shall refer to it as an $O(n)$ algorithm. The **ABA** was developed by Featherstone [3.1] and is an example of a constraint-propagation algorithm. Given the joint position, velocity, and applied torque/force variables, this algorithm calculates the joint accelerations. With the joint accelerations determined, numerical integration may be used to provide a simulation of the mechanism.

The key concept in the **ABA** is illustrated in Fig. 3.7. The subtree rooted at link i interacts with the rest of the kinematic tree only through a force \mathbf{f}_i that is transmitted across joint i . Suppose we break the tree at this point, and consider only the motion of the subtree subject to an unknown force, \mathbf{f}_i , acting on link i . It is possible to show that the acceleration of link i is related to the applied force according to the equation

$$\mathbf{f}_i = \mathbf{I}_i^A \mathbf{a}_i + \mathbf{p}_i^A, \quad (3.79)$$

where \mathbf{I}_i^A is called the articulated-body inertia of link i in the subtree (which we can now call an articulated body), and \mathbf{p}_i^A is the associated bias force, which is the force required to produce zero acceleration in link i . Note that \mathbf{p}_i^A depends on the velocities of the individual bodies in the articulated body. Equation (3.79) takes into account the complete dynamics of the subtree. Thus, if we happened to know the correct value of \mathbf{f}_i , then (3.79)

would immediately give us the correct acceleration of link i .

The reason we are interested in the quantities I_i^A and \mathbf{p}_i^A is that they allow us to calculate $\ddot{\mathbf{q}}_i$ from $\mathbf{a}_{p(i)}$, which in turn allows us to calculate \mathbf{a}_i , which then allows us to calculate more joint accelerations, and so on. Combining (3.79) with (3.75) and (3.72) gives

$$\boldsymbol{\tau}_i = \boldsymbol{\Phi}_i^T \mathbf{f}_i = \boldsymbol{\Phi}_i^T (I_i^A (\mathbf{a}_{p(i)} + \boldsymbol{\Phi}_i \ddot{\mathbf{q}}_i + \dot{\boldsymbol{\Phi}}_i \dot{\mathbf{q}}_i) + \mathbf{p}_i^A),$$

which can be solved for $\ddot{\mathbf{q}}_i$ to give

$$\ddot{\mathbf{q}}_i = \mathbf{D}_i (\mathbf{u}_i - \mathbf{U}_i^T \mathbf{a}_{p(i)}), \quad (3.80)$$

where

$$\begin{aligned} \mathbf{U}_i &= I_i^A \boldsymbol{\Phi}_i, \\ \mathbf{D}_i &= (\boldsymbol{\Phi}_i^T \mathbf{U}_i)^{-1} = (\boldsymbol{\Phi}_i^T I_i^A \boldsymbol{\Phi}_i)^{-1}, \\ \mathbf{u}_i &= \boldsymbol{\tau}_i - \mathbf{U}_i^T \boldsymbol{\zeta}_i - \boldsymbol{\Phi}_i^T \mathbf{p}_i^A \end{aligned}$$

and

$$\boldsymbol{\zeta}_i = \dot{\boldsymbol{\Phi}}_i \dot{\mathbf{q}}_i = \ddot{\boldsymbol{\Phi}}_i \dot{\mathbf{q}}_i + \mathbf{v}_i \times \boldsymbol{\Phi}_i \dot{\mathbf{q}}_i.$$

\mathbf{a}_i can then be calculated via (3.72).

It turns out that the articulated-body inertias and bias forces can be calculated efficiently via the recursive formulae

$$I_i^A = I_i + \sum_{j \in c(i)} (I_j^A - \mathbf{U}_j \mathbf{D}_j \mathbf{U}_j^T) \quad (3.81)$$

and

$$\mathbf{p}_i^A = \mathbf{p}_i + \sum_{j \in c(i)} (\mathbf{p}_j^A + I_j^A \boldsymbol{\zeta}_j + \mathbf{U}_j \mathbf{D}_j \mathbf{u}_j), \quad (3.82)$$

where

$$\mathbf{p}_i = \mathbf{v}_i \times I_i \mathbf{v}_i - \mathbf{f}_i^c.$$

These formulae are obtained by examining the relationship between \mathbf{f}_i and \mathbf{a}_i in Fig. 3.7 and assuming that I_j^A and \mathbf{p}_j^A are already known for every $j \in c(i)$. For more details see [3.1, 8, 15, 25].

The complete algorithm is shown in Algorithm 3.4.

Algorithm 3.4 Articulated-body algorithm for forward dynamics

inputs: $\mathbf{q}, \dot{\mathbf{q}}, \boldsymbol{\tau}, model, {}^0\mathbf{f}_i^c$
output: $\ddot{\mathbf{q}}$
model data: $N_B, jtype(i), p(i), X_L(i), I_i$

$\mathbf{v}_0 = \mathbf{0}$

   $\ddot{\mathbf{q}}_i = \mathbf{D}_i (\mathbf{u}_i - \mathbf{U}_i^T \mathbf{a}_i)$ 
   $\mathbf{a}_i = \mathbf{a}_i + \boldsymbol{\Phi}_i \ddot{\mathbf{q}}_i + \boldsymbol{\zeta}_i$ 
end for

```

It is expressed in link coordinates, as per the RNEA in Algorithm 3.2. It makes a total of three passes through the kinematic tree. The first pass iterates from the base out to the tips; it calculates the link velocities using (3.76), the velocity-product term $\boldsymbol{\zeta}_i = \ddot{\boldsymbol{\Phi}}_i \dot{\mathbf{q}}_i$, and it initializes the variables I_i^A and \mathbf{p}_i^A to the values I_i and $\mathbf{p}_i (= \mathbf{v}_i \times I_i \mathbf{v}_i - {}^iX_0^T {}^0\mathbf{f}_i^c)$, respectively. The second pass iterates from the tips back to the base; it calculates the articulated-body inertia and bias force for each link using (3.81) and (3.82). The third pass iterates from the base to the tips; it calculates the link and joint accelerations using (3.80) and (3.77).

Fig. 3.7 Definition of articulated body i

3.5.3 The Composite-Rigid-Body Algorithm

The **CRBA** is an algorithm for calculating the joint-space inertia matrix (**JSIM**) of a kinematic tree. The most common use for the **CRBA** is as part of a forward dynamics algorithm. It first appeared as method 3 in [3.5].

Forward dynamics, in joint space, is the task of calculating $\ddot{\mathbf{q}}$ from \mathbf{q} , $\dot{\mathbf{q}}$, and $\boldsymbol{\tau}$. Starting from (3.37), the most obvious way to proceed is to calculate \mathbf{H} and $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$, and then solve the linear equation

$$\mathbf{H}\ddot{\mathbf{q}} = \boldsymbol{\tau} - (\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g) \quad (3.83)$$

for $\ddot{\mathbf{q}}$. If the mechanism is a kinematic tree, then \mathbf{H} and $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ can be computed in $O(n^2)$ and $O(n)$ operations, respectively, and (3.83) can be solved in $O(n^3)$ operations. Algorithms that take this approach are therefore known collectively as $O(n^3)$ algorithms. However, this figure of $O(n^3)$ should be regarded as the worst-case complexity, since the actual complexity depends on the amount of branching in the tree [3.26]. Furthermore, even in the worst case, the n^3 term has a small coefficient, and does not dominate until approximately $n = 60$.

$\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ can be calculated using an inverse dynamics algorithm. If $ID(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ is the result of an inverse dynamics calculation with arguments \mathbf{q} , $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$, then

$$ID(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}) = \boldsymbol{\tau} = \mathbf{H}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g,$$

so

$$\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g = ID(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{0}). \quad (3.84)$$

Thus, the value of $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ for a kinematic tree can be calculated efficiently using the **RNEA** with $\ddot{\mathbf{q}} = \mathbf{0}$.

The key concept in the **CRBA** is to note that the **JSIM** only depends on the joint positions, and not their rates. The **CRBA** makes the simplifying assumption that the rate at each joint is zero. By also assuming that gravity is zero, $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ is eliminated from (3.83). Furthermore, for a revolute joint, a unit of joint acceleration applied at the j -th joint produces the j -th column of the **JSIM**. This partitions the mechanism into two composite rigid bodies connected by the j -th joint, and simplifies the dynamics considerably. This concept has been generalized so that the **CRBA** may be applied to any joint type within a kinematic tree structure.

It can be shown that the general form of the **JSIM** for a kinematic tree is

$$H_{ij} = \begin{cases} \Phi_i^T I_i^C \Phi_j & \text{if } i \in c^*(j) \\ \Phi_i^T I_j^C \Phi_j & \text{if } j \in c^*(i) \\ \mathbf{0} & \text{otherwise,} \end{cases} \quad (3.85)$$

where $c^*(i)$ is the set of links in the subtree rooted at link i , including link i itself, and

$$I_i^C = \sum_{j \in c^*(i)} I_j. \quad (3.86)$$

See [3.8, 15]. In fact, I_i^C is the inertia of the composite rigid body formed by the rigid assembly of all the links in $c^*(i)$, and this is where the algorithm gets its name.

Equations (3.85) and (3.86) are the basis of the algorithm shown in Algorithm 3.5, which is the **CRBA** in link coordinates.

Algorithm 3.5 Composite-rigid-body algorithm for calculating the JSIM

inputs: model, **RNEA** partial results

output: \mathbf{H}

model data : $N_B, p(i), I_i$

RNEA data : $\Phi_i, {}^iX_{p(i)}$

$\mathbf{H} = \mathbf{0}$

for $i = 1$ **to** N_B **do**

$I_i^C = I_i$

end for

for $i = N_B$ **to** 1 **do**

$\mathbf{F} = I_i^C \Phi_i$

$\mathbf{H}_{ii} = \Phi_i^T \mathbf{F}$

if $p(i) \neq 0$ **then**

$I_{p(i)}^C = I_{p(i)}^C + {}^iX_{p(i)}^T I_i^C {}^iX_{p(i)}$

end if

$j = i$

while $p(j) \neq 0$ **do**

$\mathbf{F} = {}^jX_{p(j)}^T \mathbf{F}$

$j = p(j)$

$\mathbf{H}_{ij} = \mathbf{F}^T \Phi_j$

$\mathbf{H}_{ji} = \mathbf{H}_{ij}^T$

end while

end for

This algorithm assumes that the matrices ${}^iX_{p(i)}$ and Φ_i have already been calculated, e.g., during the calculation of $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$. If this is not the case, then the relevant lines from Algorithm 3.2 can be inserted into the first loop. The matrix \mathbf{F} is a local variable. The first step, $\mathbf{H} = \mathbf{0}$, can be omitted if there are no branches in the tree.

Having calculated $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ and \mathbf{H} , the final step is to solve (3.83) for $\ddot{\mathbf{q}}$. This can be done using a standard Cholesky or **LDL**^T factorization. Note that \mathbf{H} can be highly ill-conditioned [3.27], reflecting an underlying ill-conditioning of the kinematic tree itself, so it is recommended to use double-precision arithmetic for every step in the forward dynamics calculation. (This advice applies also to the **ABA**.)

Exploiting Sparsity

Equation (3.85) implies that some elements of \mathbf{H} will automatically be zero if there are branches in the kinematic tree. An example of this effect is shown in Fig. 3.8. Observe that nearly half of the elements are zero. It is possible to exploit this sparsity using the factorization algorithms described in [3.26]. Depending on the amount of branching in the tree, the sparse algorithms can run many times faster than the standard algorithms.

3.5.4 Operational-Space Inertia Matrix

Two different algorithms are presented to calculate the OSIM. The first is an $O(n^3)$ algorithm that uses the basic definition of the OSIM along with efficient factorization of the JSIM. The second is an $O(n)$ algorithm that is based on efficient solution of the forward dynamics problem.

Algorithm Using Basic Definition

If a robot has a relatively small number of freedoms (e.g., six), then the most efficient method for calculating the OSIM is via (3.52). The procedure is as follows:

1. Calculate \mathbf{H} via the CRBA.
2. Factorize \mathbf{H} into $\mathbf{H} = \mathbf{L}\mathbf{L}^T$ (Cholesky factorization).
3. Use back-substitution to calculate $\mathbf{Y} = \mathbf{L}^{-1}\mathbf{J}^T$.
4. $\mathbf{A}^{-1} = \mathbf{Y}^T\mathbf{Y}$.
5. Factorize \mathbf{A}^{-1} (optional).

The final step is only possible if the end-effector has a full six DOFs, and is only necessary if the application requires \mathbf{A} rather than \mathbf{A}^{-1} . In the second step, an \mathbf{LDL}^T factorization can be used instead of Cholesky, or one can use one of the efficient factorizations described in [3.26] for branched kinematic trees.

The other terms in (3.38) can be calculated via (3.53) and (3.54). In particular, (3.38) can be rewritten in the form

$$\dot{\mathbf{v}} + \mathbf{A}^{-1}(\mathbf{x})[\boldsymbol{\mu}(\mathbf{x}, \mathbf{v}) + \boldsymbol{\rho}(\mathbf{x})] = \mathbf{A}^{-1}(\mathbf{x})\mathbf{f}, \quad (3.87)$$

Fig. 3.8 Branch-induced sparsity: branches in the kinematic tree cause certain elements in the JSIM to be zero

and the quantity $\mathbf{A}^{-1}(\boldsymbol{\mu} + \boldsymbol{\rho})$ can be calculated from the formula

$$\mathbf{A}^{-1}(\boldsymbol{\mu} + \boldsymbol{\rho}) = \mathbf{J}\mathbf{H}^{-1}(\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g) - \dot{\mathbf{J}}\dot{\mathbf{q}}. \quad (3.88)$$

The term $\dot{\mathbf{J}}\dot{\mathbf{q}}$ is the velocity-product acceleration of the end-effector (3.50). It is calculated as a by-product of calculating $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ via the RNEA (3.84). Specifically, $\dot{\mathbf{J}}\dot{\mathbf{q}} = \mathbf{a}_{ee} - \mathbf{a}_0$, where \mathbf{a}_{ee} is the calculated acceleration of the end-effector (expressed in the same coordinates as $\dot{\mathbf{v}}$) and \mathbf{a}_0 is the acceleration of the base ($-\mathbf{a}_g$).

$O(n)$ Algorithm

For a sufficiently large value of n , it becomes more efficient to use an $O(n)$ algorithm. Several such algorithms can be found in [3.28–30]. In this section, a more straightforward algorithm is given, which is based on an $O(n)$ calculation of the joint-space forward dynamics problem, e.g., via the ABA. It is a variation of the unit force method [3.29] and computes the inverse of the OSIM.

Starting with (3.87), observe that \mathbf{A}^{-1} is a function of position only, and certain terms in the dynamic equations can be neglected without affecting its value. Specifically, if the joint rates, $\dot{\mathbf{q}}$, joint forces, $\boldsymbol{\tau}$, and gravitational forces are all set to zero, the value of \mathbf{A} will remain unchanged. Under these conditions,

$$\dot{\mathbf{v}} = \mathbf{A}^{-1}\mathbf{f}. \quad (3.89)$$

Let us define $\hat{\mathbf{e}}_i$ to be a 6-D coordinate vector with a 1 in the i -th coordinate and zeros elsewhere. If we set $\mathbf{f} = \hat{\mathbf{e}}_i$ in (3.89), then $\dot{\mathbf{v}}$ will equal column i of \mathbf{A}^{-1} . Let us also define the function $FD(i, j, \mathbf{q}, \dot{\mathbf{q}}, \mathbf{a}_0, \boldsymbol{\tau}, \mathbf{f})$, which performs a forward-dynamics calculation and returns the true acceleration of link i (i.e., $\mathbf{a}_i - \mathbf{a}_0$), expressed in the same coordinates as \mathbf{f} (typically the base coordinates). The arguments \mathbf{q} , $\dot{\mathbf{q}}$ and $\boldsymbol{\tau}$ set the values of the joint position, velocity, and force variables, while j and \mathbf{f} specify that an external force of \mathbf{f} is to be applied to link j . The argument \mathbf{a}_0 specifies a fictitious base acceleration to include gravitational effects, and is set to either $\mathbf{0}$ or $-\mathbf{a}_g$.

With these definitions, we have

$$(\mathbf{A}^{-1})^i = FD(ee, ee, \mathbf{q}, \mathbf{0}, \mathbf{0}, \mathbf{0}, \hat{\mathbf{e}}_i) \quad (3.90)$$

and

$$\mathbf{A}^{-1}(\boldsymbol{\mu} + \boldsymbol{\rho}) = -FD(ee, ee, \mathbf{q}, \dot{\mathbf{q}}, -\mathbf{a}_g, \boldsymbol{\tau}, \mathbf{0}), \quad (3.91)$$

where $(\mathbf{A}^{-1})^i$ is column i of \mathbf{A}^{-1} , and ee is the body number of the end-effector. It therefore follows that the coefficients of (3.87) can be calculated using the algorithm shown in Algorithm 3.6. This algorithm is $O(n)$.

Algorithm 3.6 Algorithm to compute the inverse of the operational-space inertia matrix and other terms

```

for  $j = 1$  to 6 do
   $\ddot{\mathbf{v}}^j = FD(ee, ee, \mathbf{q}, \mathbf{0}, \mathbf{0}, \mathbf{0}, \hat{\mathbf{e}}_j)$ 
end for
 $\mathbf{A}^{-1} = [\ddot{\mathbf{v}}^1 \ \ddot{\mathbf{v}}^2 \ \dots \ \ddot{\mathbf{v}}^6]$ 
 $\mathbf{A}^{-1} (\boldsymbol{\mu} + \boldsymbol{\rho}) = -FD(ee, ee, \mathbf{q}, \dot{\mathbf{q}}, -\mathbf{a}_g, \boldsymbol{\tau}, \mathbf{0})$ 

```

The efficiency of the algorithm may be increased significantly when computing \mathbf{A}^{-1} by noting that: (1) \mathbf{v}_i , ξ_i , and $\boldsymbol{\tau}_i$ in the ABA calculation (Algorithm 3.4) may be set to zero, and (2) \mathbf{I}_i^A and the quantities that depend upon it (\mathbf{U}_i and \mathbf{D}_i) need only be computed once, since they do not vary with the applied force. Also, note that the algorithm may be applied to multi-

ple end-effectors by modifying FD to accept a list of end-effector body numbers in its first argument, and return a composite vector containing the accelerations of all the specified bodies. Algorithm 3.6 is then enclosed in a **for** loop that controls the second argument to FD , and iterates over all of the end-effector body numbers [3.20].

However, for the case of branched mechanisms with multiple end-effectors, several published algorithms achieve even better efficiency, and should be used instead [3.20, 29, 31–33]. The best achievable complexity is $O(n + md + m^2)$, where m is the number of end-effectors and d is the depth of the system's connectivity tree [3.33]; but the fastest algorithm for a typical humanoid exploits branch-induced sparsity [3.32, 33].

3.6 Kinematic Loops

All of the algorithms in the last section were for kinematic trees. In this section, a final algorithm is provided for the forward dynamics of closed-loop systems. The algorithm supplements the dynamic equations of motion for a spanning tree of the closed-loop system with the loop-closure constraint equations. Three different methods are given to solve the resulting linear system of equations. An efficient algorithm is given to compute the loop-closure constraints.

Systems with closed kinematic loops exhibit more complicated dynamics than kinematic trees. For example:

1. The degree of motion freedom of a kinematic tree is fixed, but that of a closed-loop system can vary.
2. The degree of instantaneous motion freedom is always the same as the degree of finite motion freedom in a kinematic tree, but they can be different in a closed-loop system.
3. Every force in a kinematic tree can be determined, but some forces in a closed-loop system can be indeterminate. This occurs whenever a closed-loop system is overconstrained.

Two examples of these phenomena are shown in Fig. 3.9. The mechanism in Fig. 3.9a has no finite motion freedom, but it has two degrees of infinitesimal motion freedom. The mechanism in Fig. 3.9b has one degree of freedom when $\theta \neq 0$, but if $\theta = 0$ then the two arms, A and B, are able to move independently, and the mechanism has two degrees of freedom. Moreover, at the boundary between these two motion regimes, the mechanism has three degrees of infinitesimal motion freedom. Both these mechanisms are planar, and are

therefore overconstrained. As a result, the out-of-plane components of the joint constraint forces are indeterminate. This kind of indeterminacy has no effect on the motions of these mechanisms, but it does complicate the calculation of their dynamics.

3.6.1 Formulation of Closed-Loop Algorithm

A closed-loop system can be modeled as a spanning tree subject to a set of loop-closure constraint forces. If

$$\mathbf{H}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g = \boldsymbol{\tau}$$

is the equation of motion of the spanning tree on its own, then the equation of motion for the closed-loop system is

$$\mathbf{H}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g = \boldsymbol{\tau} + \boldsymbol{\tau}^a + \boldsymbol{\tau}^c, \quad (3.92)$$

Fig. 3.9a,b Pathological closed-loop systems. (a) Example of varying motion freedom, (b) Example with differing finite and infinitesimal motion freedoms

where τ^a and τ^c are vectors of loop-closure active and constraint forces, respectively, expressed in the generalized force coordinates of the spanning tree. τ^a is a known quantity, and τ^c is unknown. τ^a comes from the force elements acting at the loop-closing joints (springs, dampers and actuators). If there are no such force elements, then $\tau^a = \mathbf{0}$.

The loop-closure constraints restrict the motion of the spanning tree. At the acceleration level, these constraints can be expressed in the form of a linear equation,

$$\mathbf{L}\ddot{\mathbf{q}} = \mathbf{1}, \quad (3.93)$$

where \mathbf{L} is an $n^c \times n$ matrix. n^c is the number of constraints due to the loop-closing joints, and is given by the formula

$$n^c = \sum_{k=N_B+1}^{N_J} n_k^c, \quad (3.94)$$

where n_k^c is the number of constraints imposed by joint k . If $\text{rank}(\mathbf{L}) < n^c$ then the loop-closure constraints are linearly dependent, and the closed-loop mechanism is overconstrained. The mobility of a closed-loop system (i. e., its degree of motion freedom) is given by the formula

$$\text{mobility} = n - \text{rank}(\mathbf{L}). \quad (3.95)$$

Given a constraint equation in the form of (3.93), it follows that the constraint forces can be expressed in the form

$$\tau^c = \mathbf{L}^T \lambda, \quad (3.96)$$

where $\lambda = (\lambda_{N_B+1}^T \cdots \lambda_{N_J}^T)^T$ is an $n^c \times 1$ vector of unknown constraint-force variables (or Lagrange multipliers). If the mechanism is overconstrained, then \mathbf{L}^T will have a null space, and the component of λ lying in this null space will be indeterminate.

It is often possible to identify redundant constraints in advance. For example, if a kinematic loop is known to be planar, then the out-of-plane loop-closure constraints are redundant. In these circumstances, it is advantageous to remove the corresponding rows of \mathbf{L} and elements of $\mathbf{1}$ and λ . The removed elements of λ can be assigned a value of zero.

Combining (3.92), (3.93), and (3.96) produces the following equation of motion for a closed-loop system

$$\begin{pmatrix} \mathbf{H} & \mathbf{L}^T \\ \mathbf{L} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{q}} \\ -\lambda \end{pmatrix} = \begin{pmatrix} \tau + \tau^a - (\mathbf{C}\dot{\mathbf{q}} + \tau_g) \\ \mathbf{1} \end{pmatrix}. \quad (3.97)$$

The system matrix is symmetric, but indefinite. If \mathbf{L} has full rank, then the system matrix will be nonsingular,

otherwise it will be singular, and one or more elements of λ will be indeterminate.

Equation (3.97) can be solved in any of the following ways:

1. Solve it directly for $\ddot{\mathbf{q}}$ and λ .
2. Solve for λ first, and then use the result to solve for $\ddot{\mathbf{q}}$.
3. Solve (3.93) for $\ddot{\mathbf{q}}$, substitute the result into (3.92), eliminate the unknown constraint forces, and solve for the remaining unknowns.

Method 1 is the simplest, but generally also the least efficient. This method is appropriate when the system matrix is nonsingular. As the size of the system matrix is $(n + n^c) \times (n + n^c)$, this method is $O((n + n^c)^3)$.

Method 2 is particularly useful if $n \gg n^c$, and offers the opportunity to use $O(n)$ algorithms on the spanning tree [3.6]. From (3.97),

$$\mathbf{L}\mathbf{H}^{-1}\mathbf{L}^T\lambda = \mathbf{1} - \mathbf{L}\mathbf{H}^{-1}[\tau + \tau^a - (\mathbf{C}\dot{\mathbf{q}} + \tau_g)]. \quad (3.98)$$

This equation can be formulated in $O(n(n^c)^2)$ operations via $O(n)$ algorithms, and solved in $O((n^c)^3)$. Once λ is known, τ^c can be calculated via (3.96) in $O(nn^c)$ operations, and (3.92) solved by an $O(n)$ algorithm; so the total complexity is $O(n(n^c)^2 + (n^c)^3)$. If \mathbf{L} is rank deficient, then $\mathbf{L}\mathbf{H}^{-1}\mathbf{L}^T$ will be singular; but it is still a positive-semidefinite matrix, and presents a slightly easier factorization problem than a singular instance of the indefinite system matrix in (3.97).

Method 3 is useful if $n - n^c$ is small, or if \mathbf{L} is expected to be rank deficient. Equation (3.93) is solved using a special version of Gaussian elimination (or similar procedure), which is equipped with a numerical rank test, and which is designed to solve underdetermined systems. The solution is an equation of the form

$$\ddot{\mathbf{q}} = \mathbf{K}\mathbf{y} + \ddot{\mathbf{q}}_0,$$

where $\ddot{\mathbf{q}}_0$ is any particular solution to (3.93), \mathbf{K} is an $n \times (n - \text{rank}(\mathbf{L}))$ matrix with the property $\mathbf{L}\mathbf{K} = \mathbf{0}$, and \mathbf{y} is a vector of $n - \text{rank}(\mathbf{L})$ unknowns. (Typically, \mathbf{y} is a linearly independent subset of the elements of $\ddot{\mathbf{q}}$.) Substituting this expression for $\ddot{\mathbf{q}}$ into (3.92), and pre-multiplying both sides by \mathbf{K}^T to eliminate τ^c , produces

$$\mathbf{K}^T\mathbf{H}\mathbf{K}\mathbf{y} = \mathbf{K}^T(\tau + \tau^a - (\mathbf{C}\dot{\mathbf{q}} + \tau_g) - \mathbf{H}\ddot{\mathbf{q}}_0). \quad (3.99)$$

This method also has cubic complexity, but it can be the most efficient if $n - n^c$ is small. It is also reported to be more stable than method 1 [3.34].

3.6.2 Closed-Loop Algorithm

Algorithms for calculating \mathbf{H} and $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ can be found in Sect. 3.5.3 and 3.5.1, respectively, which just leaves \mathbf{L} , \mathbf{I} and $\boldsymbol{\tau}^a$. To keep things simple, we will assume that all loop-closing joints are zero-DOF joints.

There is no loss of generality with this assumption: one simply breaks open the loops by cutting links instead of joints (Fig. 3.10). However, there may be some loss of efficiency. With this assumption, we only need to calculate \mathbf{L} and \mathbf{I} , since $\boldsymbol{\tau}^a = \mathbf{0}$.

Loop Constraints

In the general case, the velocity constraint equation for loop k is

$$(\boldsymbol{\psi}_k^c)^T (\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)}) = \mathbf{0}, \quad (3.100)$$

and the acceleration constraint is

$$(\boldsymbol{\psi}_k^c)^T (\mathbf{a}_{s(k)} - \mathbf{a}_{p(k)}) + (\dot{\boldsymbol{\psi}}_k^c)^T (\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)}) = \mathbf{0}. \quad (3.101)$$

However, if every loop-closing joint has zero DOF, then these equations simplify to

$$\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)} = \mathbf{0} \quad (3.102)$$

and

$$\mathbf{a}_{s(k)} - \mathbf{a}_{p(k)} = \mathbf{0}. \quad (3.103)$$

Let us define a loop Jacobian, \mathbf{J}_k , with the property that

$$\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)} = \mathbf{J}_k \dot{\mathbf{q}}. \quad (3.104)$$

\mathbf{J}_k is a $6 \times n$ matrix defined by the formula

$$\mathbf{J}_k = (e_{1k} \boldsymbol{\Phi}_1 \cdots e_{N_B k} \boldsymbol{\Phi}_{N_B}), \quad (3.105)$$

Fig. 3.10 Inserting a zero-DOF joint in preparation for cutting the loop open at that joint

where

$$e_{ik} = \begin{cases} +1 & \text{if } s(k) \in c^*(i) \text{ and } p(k) \notin c^*(i), \\ -1 & \text{if } p(k) \in c^*(i) \text{ and } s(k) \notin c^*(i), \\ 0 & \text{otherwise.} \end{cases}$$

In other words, $e_{ik} = +1$ if joint i lies on the path to $s(k)$ but not the path to $p(k)$; $e_{ik} = -1$ if joint i lies on the path to $p(k)$ but not the path to $s(k)$; and $e_{ik} = 0$ if joint i lies on both paths or on neither.

The loop acceleration constraint can now be written

$$\begin{aligned} \mathbf{0} &= \mathbf{a}_{s(k)} - \mathbf{a}_{p(k)} \\ &= \mathbf{J}_k \ddot{\mathbf{q}} + \dot{\mathbf{J}}_k \dot{\mathbf{q}} \\ &= \mathbf{J}_k \ddot{\mathbf{q}} + \mathbf{a}_{s(k)}^{\text{vp}} - \mathbf{a}_{p(k)}^{\text{vp}}, \end{aligned} \quad (3.106)$$

where \mathbf{a}_i^{vp} is the velocity-product acceleration of link i , which is the acceleration it would have if $\ddot{\mathbf{q}}$ were zero. The velocity-product acceleration of every link is calculated during the calculation of the vector $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ (3.84). If the RNEA is used to calculate $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$, then \mathbf{a}_i^{vp} will be the value of \mathbf{a}_i calculated by the RNEA with its acceleration argument set to zero.

The matrices \mathbf{L} and \mathbf{I} can now be expressed as follows

$$\mathbf{L} = \begin{pmatrix} \mathbf{L}_{N_B+1} \\ \vdots \\ \mathbf{L}_{N_J} \end{pmatrix} \quad \text{and} \quad \mathbf{I} = \begin{pmatrix} \mathbf{I}_{N_B+1} \\ \vdots \\ \mathbf{I}_{N_J} \end{pmatrix}, \quad (3.107)$$

where

$$\mathbf{L}_k = \mathbf{J}_k \quad (3.108)$$

and

$$\mathbf{I}_k = \mathbf{a}_{p(k)}^{\text{vp}} - \mathbf{a}_{s(k)}^{\text{vp}}. \quad (3.109)$$

Constraint Stabilization

In practice, it is necessary to stabilize loop-closure constraints, or they will simply fly apart during simulation because of numerical integration errors. The standard technique is due to *Baumgarte* [3.3, 7, 35], and consists of replacing each constraint equation of the form

$$a_e = 0,$$

with one of the form

$$a_e + K_v v_e + K_p p_e = 0,$$

where a_e , v_e , and p_e are the acceleration, velocity, and position errors, respectively, and K_v and K_p are positive constants. Typically, one chooses a time constant,

t_c , according to how quickly one wants the position and velocity errors to decay. K_p and K_v are then given by the formulae $K_v = 2/t_c$ and $K_p = 1/t_c^2$. However, there is no good rule for choosing t_c . If t_c is too long, then loop-constraint errors accumulate faster than they decay; if t_c is too short, then the equations of motion become excessively stiff, causing a loss of numerical integration accuracy. A reasonable value for a large, slow industrial robot is $t_c = 0.1$, while a smaller, faster robot might need $t_c = 0.01$.

To incorporate stabilization terms into the loop constraint equation, we replace (3.109) with

$$\mathbf{l}_k = \mathbf{a}_{p(k)}^{\text{vp}} - \mathbf{a}_{s(k)}^{\text{vp}} - K_v(\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)}) - K_p \mathbf{p}_{ek}, \quad (3.110)$$

where \mathbf{p}_{ek} is a vector representing the position error in loop k . In absolute coordinates (i. e., link 0 coordinates), \mathbf{p}_{ek} is given by

$$\mathbf{p}_{ek} = \mathbf{x_to_vec}({}^0X_{p(k)} X_{L1}^{-1}(k) X_{L2}(k) {}^{s(k)}X_0), \quad (3.111)$$

where the $X_{L1}(k)$ and $X_{L2}(k)$ transforms are defined in (3.62) and (3.63), and shown in Fig. 3.4 for joint k , and $\mathbf{x_to_vec}({}^B X_A)$ computes a vector approximating the displacement from frame A to frame B , assuming this displacement to be infinitesimal. $\mathbf{x_to_vec}$ can be defined as

$$\mathbf{x_to_vec}(X) = \frac{1}{2} \begin{pmatrix} X_{23} - X_{32} \\ X_{31} - X_{13} \\ X_{12} - X_{21} \\ X_{53} - X_{62} \\ X_{61} - X_{43} \\ X_{42} - X_{51} \end{pmatrix}. \quad (3.112)$$

Algorithm

Algorithm 3.7 shows an algorithm for calculating \mathbf{L} and \mathbf{l} for the special case when all the loop-closing joints have 0-DOF. It combines simplicity with good performance by transforming every quantity that is needed to formulate the loop-closure constraints into a single coordinate system, in this case absolute (link 0) coordinates, so that no further transforms are needed.

The first loop calculates the transforms from absolute to link coordinates, and uses them to transform Φ_i

to absolute coordinates. Only the Φ_i that are needed in the loop-closure constraints are transformed.

The second loop calculates the nonzero elements of \mathbf{L} (which can be sparse), according to (3.105). The inner while loop terminates on the root of the loop, which is the highest-numbered common ancestor of links $p(k)$ and $s(k)$. It could be the fixed base if they have no other common ancestor. The second loop ends with the calculation of \mathbf{l} , in absolute coordinates, according to (3.110).

3.7 Conclusions and Further Reading

This chapter has presented the fundamentals of rigid-body dynamics as they apply to robot mechanisms. It has covered the following topics: the spatial vector al-

gebra, which provides a concise notation for describing and implementing dynamics equations and algorithms; the canonical equations of motion that are most fre-

quently used in robotics; how to construct a dynamic model of a robot; and several efficient model-based algorithms for calculating inverse dynamics, forward dynamics, and the joint-space and operational-space inertia matrices.

There are many topics in dynamics that have not been mentioned in this chapter, but can be found in later chapters of this handbook. The dynamics of robots with elastic links and joints is covered in Chap. 11; the problem of identifying the parameters of a dynamic model is covered in Chap. 6; the dynamics of physical contact between a robot and the objects in its environment is described in Chap. 37; and the dynamics of robots with floating bases is described in Chap. 55.

We conclude this chapter by noting that a brief history of robot dynamics can be found in [3.36], and that a more extensive treatment of robot dynamics can be found in books such as [3.8, 10, 15, 29, 37–40]. Finally, some suggestions for further reading are listed below.

3.7.1 Multibody Dynamics

Robot dynamics can be regarded as a subset (or a specific application) of the broader discipline of multibody dynamics. Books on multibody dynamics include [3.3, 14, 35, 41–46]. Of course, multibody dynamics is, in turn, a subset of classical mechanics; and the mathematical foundations of the subject can be found in any good book on classical mechanics, such as [3.13].

3.7.2 Alternative Representations

This chapter has used spatial vectors to express the equations of motion. There are various alternatives to the use of spatial vectors: other kinds of 6-D vector, 3-D vectors, 4×4 matrices, and the spatial operator algebra. All 6-D vector formalisms are similar, but are not exactly the same. The main alternatives to spatial vectors are: screws [3.10–12], motors [3.47], Lie algebras [3.12, 48], and ad hoc notations. (An ad hoc notation is one in which 3-D vectors are grouped into pairs for the purpose of reducing the volume of algebra.) Three-dimensional vectors are the formalism used in most classical mechanics and multibody texts, and are also a precursor to 6-D vector and 4×4 matrix formalisms. 4×4 matrices are popular in robotics because they are very useful for kinematics. However, they are not so useful for dynamics. 4×4 matrix formulations of dynamics can be found in [3.37, 49, 50]. The spatial operator algebra was developed at the Jet Propulsion Laboratory (JPL) by Rodriguez, Jain, and others. It uses $6N$ -dimensional vectors and $6N \times 6N$ matrices, the latter regarded as linear operators. Examples of this notation can be found in [3.38, 51–53].

3.7.3 Alternative Formulations

This chapter used a vectorial formulation of the equations of motion that is usually called the Newtonian or Newton–Euler formulation. The main alternative is the Lagrangian formulation, in which the equations of motion are obtained via Lagrange’s equation. Examples of the Lagrangian formulation can be found in [3.9, 10, 18, 54, 55]. Kane’s method has also been applied in robotics [3.56, 57].

3.7.4 Efficiency

Because of the need for real-time implementation, especially in control, the robotics community has focused on the problem of computational efficiency. For *inverse dynamics*, the $O(n)$ recursive Newton–Euler algorithm (RNEA) of Luh et al. [3.4] remains the most important algorithm. Further improvements to the algorithm are given in [3.58, 59]. For *forward dynamics*, the two algorithms presented in this chapter remain the most important for computational considerations: the $O(n)$ articulated-body algorithm (ABA) developed by Featherstone [3.1] and the $O(n^3)$ algorithm based on the composite-rigid-body algorithm (CRBA) of Walker and Orin [3.5]. Improvements were made in the ABA over the years [3.15, 17, 25] so that it was more efficient than the CRBA-based algorithm for decreasingly smaller values of n . However, more recent application of the CRBA to branched kinematic trees [3.26] and robotic systems with motion-controlled appendages [3.60] continue to show the viability of the CRBA approach.

For the *joint-space inertia matrix*, the CRBA [3.5] is the most important algorithm. A number of improvements and modifications have been made over the years to increase its computational efficiency [3.15, 61–63]. For the *operational-space inertia matrix*, efficient $O(n)$ algorithms have been developed [3.28–30] and applied to increasingly complex systems [3.20, 31, 33]. The exploitation of branch-induced sparsity also results in an efficient algorithm [3.32].

3.7.5 Accuracy

Concerns can arise over the numerical accuracy of a dynamics algorithm, the accuracy of a simulation (i.e., numerical integration accuracy), or the accuracy of a dynamic model. The numerical accuracy of dynamics algorithms has received relatively little attention compared with efficiency. The RNEA, CRBA, and ABA have all been tested for accuracy on a large variety of rigid-body systems, but the same cannot be said of most other algorithms. Rigid-body systems are often ill-conditioned, in the sense that a small change

in the applied force (or a model parameter) can produce a large change in the resulting acceleration. This phenomenon was studied by *Featherstone* [3.27], who discovered that the ill-conditioning gets worse with increasing body count, and that it can grow in proportion to $O(n^4)$ in the worst case. Other publications on this topic include [3.8, 34, 64, 65].

3.7.6 Software Packages

A number of software packages have been developed to provide dynamic simulation capabilities for multibody systems, and in particular, robotic systems. Several have been written in MATLAB for ease of integration with other analysis, control, and simulation programs. Many packages are open source, and some are offered at a relatively low cost to the user. They differ in their capabilities in a variety of ways including: speed, topologies and joint models supported, accuracy, underlying dynamic formulation and associated order of complexity, user interface, graphics support, numerical integration routines, integration with other code, application support, and cost. Among those commonly cited are: Adams [3.66], Autolev [3.67], Bullet [3.68], DART [3.69], DynaMechs [3.70], Gazebo [3.71], Open Dynamics Engine [3.72], Robotics Studio [3.73], Robotics Toolbox [3.74], Robotran [3.75, 76], SD/FAST [3.77], Simbody [3.78], SimMechanics [3.79], SYMORO [3.80, 81] and Webots [3.82].

3.7.7 Symbolic Simplification

The technique of symbolic simplification takes a general-purpose dynamics algorithm, and applies it symbolically to a specific dynamic model. The result is a list of assignment statements detailing what the algorithm would have done if it had been executed for real. This list is then inspected and pruned of all unnecessary calculations, and the remainder is output to a text file in the form of computer source code. This code can run as much as ten times faster than the original general-purpose algorithm, but it is specific to one dynamic model. Both Autolev [3.67] and SD/FAST [3.77] use

this technique. Other publications on symbolic simplification for dynamics include [3.76, 80, 81, 83–88].

3.7.8 Algorithms for Parallel Computers

In order to speed up the common dynamics computations, a number of algorithms have been developed for parallel and pipelined computers. For *inverse dynamics*, early work focused on speeding up the $O(n)$ RNEA on up to n processors [3.89, 90] while subsequent work resulted in $O(\log_2 n)$ algorithms [3.91, 92]. For the $O(n^2)$ CRBA to compute the *joint-space inertia matrix*, early work resulted in $O(\log_2 n)$ algorithms for n processors to compute the composite-rigid-body inertias and diagonal elements of the matrix [3.93, 94]. Subsequent work resulted in $O(\log_2 n)$ algorithms for $O(n^2)$ processors to compute the entire matrix [3.95, 96]. For *forward dynamics*, speedup was obtained for a multiple manipulator system on a parallel/pipelined supercomputer [3.97]. The first $O(\log_2 n)$ algorithm for n processors was developed for an unbranched serial chain [3.98]. More recent work has focused on $O(\log_2 n)$ algorithms for more complex structures [3.65, 99, 100].

3.7.9 Topologically-Varying Systems

There are many robot mechanisms whose topology varies over time because of a change of contact conditions, especially with the environment. In legged vehicles, use of a compliant ground-contact model to compute the contact forces reduced the closed-loop structure to a tree structure [3.101]. However, for cases in which the contacts are very stiff, numerical integration problems may result. In more recent work [3.40, 102] in which hard contact constraints are assumed, an efficient method was used to reduce the large number of coordinate variables from that which may be necessary in general-purpose motion analysis systems [3.43]. Also, they were able to automatically identify the variables as the structure varied and developed a method for computing the velocity boundary conditions after configuration changes [3.40, 102].

4. Mechanism and Actuation

Victor Scheinman, J. Michael McCarthy, Jae-Bok Song

This chapter focuses on the principles that guide the design and construction of robotic systems. The kinematics equations and Jacobian of the robot characterize its range of motion and mechanical advantage, and guide the selection of its size and joint arrangement. The tasks a robot is to perform and the associated precision of its movement determine detailed features such as mechanical structure, transmission, and actuator selection. Here we discuss in detail both the mathematical tools and practical considerations that guide the design of mechanisms and actuation for a robot system.

The following sections (Sect. 4.1) discuss characteristics of the mechanisms and actuation that affect the performance of a robot. Sections 4.2–4.6 discuss the basic features of a robot manipulator and their relationship to the mathematical model that is used to characterize its performance. Sections 4.7 and 4.8 focus on the details of the structure and actuation of the robot and how they combine to yield various types of robots. The final Sect. 4.9 relates these design features to various performance metrics.

4.1 Overview

The physical structure such as the beams, links, castings, shafts, slides, and bearings of a robot that create its movable skeleton is termed the mechanical structure or mechanism of the robot. The electric, hydraulic and pneumatic motors and other elements that cause the links of the mechanism to move are called actuators. In this chapter we consider the variety of designs for the mechanisms and actuators that result in a machine system that transforms computer commands into versatile physical movement.

Early robots were designed with general motion capability under the assumption that they would find the largest market if they could perform the widest variety of tasks; this emphasis on flexibility proved to be expensive in both cost and performance. Robots are now often designed for specific applications and to perform limited sets of tasks.

Robot design focuses on the number of joints, physical size, payload capacity, and the movement re-

quirements of the end-effector. The configuration of the movable skeleton and the overall size of the robot are determined by task requirements for reach, workspace, and reorientation ability. These features affect the precision of end-effector path control needed for applications such as for arc-welding and for the smooth movement of paint spraying. They also define the absolute positioning capability necessary for small part assembly, the repeatability needed for material and package handling, and the fine resolution that allows precise, real-time sensor-based motions.

A critical concern in robotic system design is the range of tasks the robot is expected to perform. The robot should be designed to have the flexibility it needs to perform the range of tasks for which it is intended. This determines the topology of the robot mechanism and the actuator system. The choices of geometry, material, sensors, and cable routing follow from these basic decisions.

4.2 System Features

The primary features that characterize a robot are its work envelope and load capacity.

4.2.1 Work Envelope

The space in which a robot can operate is its work envelope, which encloses its workspace. While the workspace of the robot defines positions and orientations that it can achieve to accomplish a task, the work envelope also includes the volume of space the robot itself occupies as it moves. This envelope is defined by the types of joints, their range of movement and the lengths of the links that connect them. The physical size of this envelope and the loads on the robot within this envelope are of primary consideration in the design of the mechanical structure of a robot.

Robot work envelope layouts must include considerations of regions of limited accessibility where the mechanical structure may experience movement limitations. These constraints arise from limited joint travel range, link lengths, the angles between axes, or a combination of these. Revolute joint manipulators generally work better in the middle of their work envelopes than at extremes (Fig. 4.1). Manipulator link lengths and joint travel should be chosen to leave margins for variable sensor-guided controlled path motions and for tool or end-effector changes, as offsets and length differences will often alter the work envelope.

4.2.2 Load Capacity

Load capacity, a primary robot specification, is closely coupled with acceleration and speed. For assembly robots, mechanism acceleration and stiffness (structure and drive stiffness) are often more important design parameters than peak velocity or maximum load capacity, as minimizing pick-and-place motion cycle time, while maintaining placement precision, is generally a top priority in small part assembly. In the case of arc-welding, where slow controlled-path motion is required, velocity

Fig. 4.1 The PUMA 560 robot

jitter and weld path-following accuracy are important. Load capacity should be seen as a variable. It is wise to design and specify a manipulator in terms of useful payload as a function of performance rather than just in terms of maximum capacity.

Load capacity specifications must take into account gravity and inertial loading seen at the end-effector. These factors strongly affect wrist, end-effector design and drive selection. In general, load capacity is more a function of manipulator acceleration and wrist torque than any other factor. The load rating also affects manipulator static structural deflection, steady-state motor torque, system natural frequency, damping, and the choice of control system parameters for best performance and stability.

4.2.3 Kinematic Skeleton

Manipulator shape and size is determined by requirements on its workspace shape and layout, the precision of its movement, its acceleration and speed, and its construction. Cartesian manipulators have the simplest transform and control equation solutions. Their prismatic (straight-line motion) and orthogonal (perpendicular) axes make motion planning and computation relatively straightforward. Because their major motion axes do not couple dynamically (to a first order), their control equations are also simplified. Manipulators with all revolute (rotary) joints are generally harder to control, but they feature a more compact and efficient structure for a given working volume. It is generally easier to de-

sign and build a good revolute joint than a long motion prismatic joint. The workspaces of revolute joint manipulators can easily overlap for coordinated multi-robot installations, in contrast to the more exclusive useful workspace of gantry style robots.

Final selection of the robot configuration should capitalize on specific kinematic, structural or performance requirements. For example, a requirement for a very precise vertical straight-line motion may dictate the choice of a simple prismatic vertical axis rather than two or three revolute joints requiring coordinated control.

Six degrees of freedom (DOFs) are the minimum required to place the end-effector or tool of a robotic manipulator at any arbitrary location (position and orientation) within its accessible workspace. Most simple or preplanned tasks can be performed with fewer than six DOFs by careful task setup to eliminate certain axis motions, or because the tool or task does not require full specification of location. An example of this is vertical assembly using a powered screwdriver, where all operations can be achieved with three degrees of freedom.

Some applications require the use of manipulators with more than six DOFs, in particular when mobility or obstacle avoidance are necessary. For example, a pipe-crawling maintenance robot requires control of the robot shape as well as precise positioning of its end-effector. Generally, adding degrees of freedom increases cycle time and reduces load capacity and accuracy for a given manipulator configuration and drive system.

4.3 Kinematics and Kinetics

The dynamics of a robot can be separated into the properties of the movement that depend upon the geometry of its mechanical structure, termed *kinematics*, and those that depend on forces that act on the system, known as *kinetics*. It is a law of dynamics that the difference between the change in energy of the moving robot and the work performed by the forces acting on it does not change over small variations of its trajectory. This is called the *principle of virtual work* and states that variations in work and energy must cancel for all virtual displacements [4.1, 2].

Because machines such as robots are designed to minimize energy losses, often due to joint friction and material strain losses, we can assume that the variation in energy is small. This means that the work input of the actuators is nearly equal to the work of the output forces.

If we consider this relationship over a small duration of time, we have that the time rate of input work,

or input power is nearly equal to the associated output power. Because power is force times velocity, we obtain the fundamental relationship that the ratio of input to output forces is the reciprocal of the ratio of input to output speeds. Another way of saying this is that, in the ideal machine, *the mechanical advantage of a machine is the inverse of its speed ratio*.

4.3.1 Robot Topology

The kinematic skeleton of a robot is modeled as a series of links connected by either hinged or sliding joints forming a serial chain. This skeleton has two basic forms, that of a single serial chain called a *serial robot* (Fig. 4.1) and as a set of serial chains supporting a single end-effector, called a *parallel robot*, such as the platform shown in Fig. 4.2. Robots can be configured to work in parallel such as the individual legs of walking machines (Figs. 4.3 and 4.4) [4.3], as

Fig. 4.2 A parallel robot can have as many as six serial chains that connect a platform to the base frame (👁 VIDEO 640)

Fig. 4.5 The Salisbury three-fingered robot hand with its cable drive system

Fig. 4.3 A photograph of the adaptive suspension vehicle (ASV) walking machine

Fig. 4.6 The Salisbury hand as the end-effector of a PUMA robot (the drive system is not shown)

Fig. 4.4 The adaptive suspension vehicle walking machine

Fig. 4.7 A photograph of the Salisbury three-fingered hand grasping a block

well as the fingers of mechanical hands (Figs. 4.5–4.7 and 👁 VIDEO 642) [4.4].

The robot end-effector is the preferred tool for interaction with the environment, and the ability to position and orient this end-effector is defined by the skeleton of

the robot. In a general serial robot, a chain of six joints provides full control over the end-effector. In a general parallel robot, there are more than six joints and the six actuators may be applied to these joints in a variety of ways to control the movement of the end-effector.

Fig. 4.8 The kinematic skeleton defined by the joint axes and their common normals

4.3.2 Kinematics Equations

A robot is designed so that specifying the values of local joint parameters, such as the angle of rotary joints and the travel of sliding joints, specifies the position of every component of a machine using its kinematics equations. To do this the robot is described by a sequence of lines representing the axes \hat{z}_j of equivalent revolute or prismatic joints and the common normal lines \hat{x}_j which form the kinematic skeleton of the chain (Fig. 4.8). This construction allows the specification of the location of each link of the robot relative to the base by the matrix equation

$$\mathbf{T} = \mathbf{Z}(\theta_1, d_1)\mathbf{X}(\alpha_1, a_1)\mathbf{Z}(\theta_2, d_2) \dots \times \mathbf{X}(\alpha_{m-1}, a_{m-1})\mathbf{Z}(\theta_m, d_m), \quad (4.1)$$

known as the *kinematics equations* of the chain [4.5, 6] (Chap. 2; (2.46)). The set of all positions \mathbf{T} that the end-effector can reach for all values of the joint parameters is called the *workspace* of the robot.

The matrices $\mathbf{Z}(\theta_j, d_j)$ and $\mathbf{X}(\alpha_j, a_j)$ are 4×4 matrices that define screw displacements around and along the joint axes \hat{z}_j and \hat{x}_j , respectively [4.7]. The parameters α_j and a_j define the dimensions of the links in the chain. The parameter θ_j is the joint variable for revolute joints and d_j is the variable for prismatic joints. The trajectory ${}^F\mathbf{p}(t)$ of a point ${}^M\mathbf{p}$ in the end-effector is obtained from the joint trajectory,

$$\mathbf{q}(t) = (q_1(t), \dots, q_m(t))^T,$$

where q_i is either θ_i or d_i depending on the joint, given by

$${}^F\mathbf{p}(t) = \mathbf{T}(\mathbf{q}(t)){}^M\mathbf{p}. \quad (4.2)$$

If the end-effector is connected to the base frame by more than one serial chain (Fig. 4.2) then we have a set of kinematics equations for each chain,

$$\mathbf{T} = \mathbf{B}_j\mathbf{T}(\mathbf{q}_j)\mathbf{E}_j, \quad j = 1, \dots, n, \quad (4.3)$$

where \mathbf{B}_j locates the base of the j -th chain and \mathbf{E}_j defines the position of its attachment to the part, or end-effector. The set of positions \mathbf{T} that simultaneously satisfy all of these equations is the workspace of the part. This imposes constraints on the joint variables that must be determined to define its workspace completely [4.8, 9].

4.3.3 Configuration Space

The kinematics equations of the robot relate the range of values available for the joint parameters, called the configuration space of the robot, to the workspace of the end-effector. This configuration space is a fundamental tool in robot path planning for obstacle avoidance [4.10]. Though any link in the chain forming a robot may hit an obstacle, it is the end-effector that is intended to approach and move around obstacles such as the table supporting the robot and the fixtures for parts it is to pick up. Obstacles define forbidden positions and orientations in the workspace which map back to forbidden joint angles in the configuration space of the robot. Robot path planners seek trajectories to a goal position through the free space around these joint space obstacles [4.11].

4.3.4 Speed Ratios

The speed ratios of a robot relate the velocity ${}^F\dot{\mathbf{p}}$ of a point ${}^F\mathbf{p}$ in the end-effector to the joint rates

$$\dot{\mathbf{q}} = (\dot{q}_1, \dots, \dot{q}_m)^T,$$

that is

$${}^F\dot{\mathbf{p}} = \mathbf{v} + \boldsymbol{\omega} \times ({}^F\mathbf{p} - \mathbf{d}), \quad (4.4)$$

where \mathbf{d} and \mathbf{v} are the position and velocity of a reference point, respectively, and $\boldsymbol{\omega}$ is the angular velocity of the end-effector.

The vectors \mathbf{v} and $\boldsymbol{\omega}$ depend on the joint rates \dot{q}_j through the formula

$$\begin{pmatrix} \mathbf{v} \\ \boldsymbol{\omega} \end{pmatrix} = \begin{pmatrix} \frac{\partial \mathbf{v}}{\partial \dot{q}_1} & \frac{\partial \mathbf{v}}{\partial \dot{q}_2} & \dots & \frac{\partial \mathbf{v}}{\partial \dot{q}_m} \\ \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_1} & \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_2} & \dots & \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_m} \end{pmatrix} \begin{pmatrix} \dot{q}_1 \\ \vdots \\ \dot{q}_m \end{pmatrix}, \quad (4.5)$$

or

$$\mathbf{v} = \mathbf{J}\dot{\mathbf{q}}. \quad (4.6)$$

The coefficient matrix \mathbf{J} in this equation is called the *Jacobian* and is a matrix of speed ratios relating the velocity of the tool to the input joint rotation rates [4.6, 9].

4.3.5 Mechanical Advantage

If the end-effector of the robot exerts a force \mathbf{f} at the point ${}^F\mathbf{p}$, then the power output is

$$P_{\text{out}} = \mathbf{f} \cdot {}^F\dot{\mathbf{p}} = \sum_{j=1}^m \mathbf{f} \cdot \left[\frac{\partial \mathbf{v}}{\partial \dot{q}_j} + \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_j} \times ({}^F\mathbf{p} - \mathbf{d}) \right] \dot{q}_j. \quad (4.7)$$

Each term in this sum is the portion of the output power that can be associated with an actuator at joint S_j , if one exists.

The power input at joint S_j is the product $\tau_j \dot{q}_j$ of the torque τ_j and joint angular velocity \dot{q}_j . Using the principle of virtual work for each joint we can compute

$$\tau_j = \mathbf{f} \cdot \frac{\partial \mathbf{v}}{\partial \dot{q}_j} + ({}^F\mathbf{p} - \mathbf{d}) \times \mathbf{f} \cdot \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_j}, \quad j = 1, \dots, m. \quad (4.8)$$

We have arranged this equation to introduce the force-torque vector

$$\mathbf{f} = (\mathbf{f}, ({}^F\mathbf{p} - \mathbf{d}) \times \mathbf{f})^T$$

at the reference point \mathbf{d} .

The equations (4.8) can be assembled into the matrix equation

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{f}, \quad (4.9)$$

where \mathbf{J} is the *Jacobian* defined above in (4.5). For a chain with six joints this equation can be solved for the output force-torque vector \mathbf{f} ,

$$\mathbf{f} = (\mathbf{J}^T)^{-1} \boldsymbol{\tau}. \quad (4.10)$$

Thus, the matrix that defines the mechanical advantage for this system is the inverse of the matrix of speed ratios.

4.4 Serial Robots

A serial chain robot is a sequence of links and joints that begins at a base and ends with an end-effector (Fig. 4.9). The links and joints of a robot are often configured to provide separate translation and orientation structures. Usually, the first three joints are used to position a reference point in space and the last three form the *wrist* which orients the end-effector around this point [4.12, 13]. This reference point is called the *wrist center*. The volume of space in which the wrist center can be placed is called the *reachable workspace* of the robot. The rotations avail-

able at each of these points is called the *dexterous workspace*.

The design of a robot is often based on the symmetry of its reachable workspace. From this point of view there are three basic shapes: rectangular, cylindrical, and spherical [4.6]. A rectangular workspace is provided by three mutually perpendicular prismatic (P) joints which form a PPPS chain called a *Cartesian* robot – S denotes a spherical wrist which allows all rotations about its center point. A rotary base joint combined with two prismatic joints forms a CPS chain with a cylindrical workspace – C denotes a rotary (R) and sliding (P) joint with the same axis. The P-joint can be replaced by a revolute (R) joint that acts as an elbow in order to provide the same radial movement. Finally, two rotary joints at right angles form a T-joint at the base of the robot that supports rotations about a vertical and horizontal axes. Radial movement is provided either by a P-joint, or by an R-joint configured as an elbow. The result is a TPS or TRS chain with a spherical workspace.

It is rare that the workspace is completely symmetrical because joint axes are often offset to avoid link collisions and there are limits to joint travel which combine to distort the shape of the workspace.

Fig. 4.9 A single finger of the Salisbury hand is a serial chain robot

4.4.1 Design Optimization

Another approach to robot design uses a direct specification of the workspace as a set of positions for the end-effector of a robotic system [4.14–17] which we call the *task space*. A general serial robot arm has two design parameters, link offset and twist, for each of five links combined with four parameters each that locate the base of the robot and the workpiece in its end-effector, making a total of 18 design variables. The link parameters are often specified so the chain has a spherical wrist and specific workspace shape. The design goal is usually to determine the workspace volume and locate the base and workpiece frames so that the workspace encloses the specified task space.

The task space is defined by a set of 4×4 transformations $\mathbf{D}_i, i = 1, \dots, k$. The problem is solved iteratively by selecting a design and using the associated kinematics equations $\mathbf{T}(\mathbf{q})$ to evaluate relative displacements in the objective function

$$f(\mathbf{r}) = \sum_{i=1}^k \|\mathbf{D}_i \mathbf{T}^{-1}(\mathbf{q}_i)\|. \quad (4.11)$$

Optimization techniques yield the design parameter vector \mathbf{r} that minimizes this objective function.

This optimization depends on the definition of the distance measure between the positions reached by the end-effector and the desired workspace. *Park* [4.18], *Martinez and Duffy* [4.19], *Zefran et al.* [4.20], *Lin and Burdick* [4.21], and others have shown that there is no distance metric that is coordinate frame invariant. This means that, unless this objective function can be forced to zero so the workspace completely contains the task space, the resulting design will not be *geometric* in the sense that the design is not independent of the choice of coordinates.

4.4.2 Speed Ratios

A six-axis robot has a 6×6 Jacobian \mathbf{J} obtained from (4.5) that is an array of speed ratios relating the

components of the velocity \mathbf{v} of the wrist center and the angular velocity $\boldsymbol{\omega}$ of the end-effector to each of the joint velocities. Equation (4.9) shows that this Jacobian defines the force-torque vector \mathbf{f} exerted at the wrist center in terms of the torque applied by each of the actuators. The link parameters of the robot can be selected to provide a Jacobian \mathbf{J} with specific properties.

The sum of the squares of the actuator torques of a robot is often used as a measure of *effort* [4.22, 23]. From (4.9) we have

$$\boldsymbol{\tau}^T \boldsymbol{\tau} = \mathbf{f}^T \mathbf{J} \mathbf{J}^T \mathbf{f}. \quad (4.12)$$

The matrix $\mathbf{J} \mathbf{J}^T$ is square and positive definite. Therefore, it can be viewed as defining a hyperellipsoid in six-dimensional space [4.24]. The lengths of the semi-diameters of this ellipsoid are the inverse of the absolute value of the eigenvalues of the Jacobian \mathbf{J} . These eigenvalues may be viewed as *modal* speed ratios that define the amplification associated with each joint velocity. Their reciprocals are the associated *modal* mechanical advantages, so the shape of this ellipsoid illustrates the force amplification properties of the robot.

The ratio of the largest of these eigenvalues to the smallest, called the condition number, gives a measure of the anisotropy or *out-of-roundness* of the ellipsoid. A sphere has a condition number of one and is termed *isotropic*. When the end-effector of a robot is in a position with an isotropic Jacobian there is no amplification of the speed ratios or mechanical advantage. This is considered to provide high-fidelity coupling between the input and output because errors are not amplified [4.25, 26]. Thus, the condition number is used as a criterion in a robot design [4.27].

In this case, it is assumed that the basic design of the robot provides a workspace that includes the task space. Parameter optimization finds the internal link parameters that yield the desired properties for the Jacobian. As in minimizing the distance to a desired workspace, optimization based on the Jacobian depends on a careful formulation to avoid coordinate dependency.

4.5 Parallel Robots

A robotic system in which two or more serial chain robots support an end-effector is called a *parallel robot*. For example, the adaptive suspension vehicle (ASV) leg (Fig. 4.10), is a pantograph mechanism driven by parallel actuation. Each supporting chain of a parallel robot may have as many as six degrees of freedom, however, in general only a total of six joints in the en-

tire system are actuated. A good example is the Stewart platform formed from six TPS robots in which usually only the prismatic joint (P-joint) in each chain is actuated (Fig. 4.2) [4.9, 28, 29].

The kinematics equations of the TPS legs are

$$\mathbf{T} = \mathbf{B}_j \mathbf{T}(\theta_j) \mathbf{E}_j, \quad j = 1, \dots, 6, \quad (4.13)$$

where \mathbf{B}_j locates the base of the leg and \mathbf{E}_j defines the position of its attachment to the end-effector. The set of positions \mathbf{T} that simultaneously satisfy all of these equations is the workspace of the parallel robot.

Often the workspace of an individual chain of a parallel robot can be defined by geometric constraints, for example, a position \mathbf{T} is in the workspace of the j -th supporting TPS chain if it satisfies the constraint equation

$$(\mathbf{T}\mathbf{x}_j - \mathbf{p}_j) \cdot (\mathbf{T}\mathbf{x}_j - \mathbf{p}_j) = \rho_j^2. \quad (4.14)$$

This equation defines the distance between the base joint \mathbf{p}_j and the point of attachment ${}^F\mathbf{x}_j = \mathbf{T}\mathbf{x}_j$ to the platform as the length ρ_j is controlled by the actuated prismatic joint. In this case the workspace is the set of positions \mathbf{T} that satisfy all six equations, one for each leg.

4.5.1 Workspace

The workspace of a parallel robot is the intersection of the workspaces of the individual supporting chains. However, it is not the intersection of the reachable and dexterous workspaces separately. These workspaces are intimately combined in parallel robots. The dexterous workspace is usually largest near the center of the reachable workspace and shrinks as the reference point moves toward the edge. A focus on the symmetry of

movement allowed by supporting leg designs has been an important design tool resulting in many novel parallel designs [4.30, 31]. Simulation of the system is used to evaluate its workspace in terms of design parameters.

Another approach is to specify directly the positions and orientations that are to lie in the workspace and solve the algebraic equations that define the leg constraints to determine the design parameters [4.32, 33]. This is known as kinematic synthesis and yields parallel robots that are asymmetric but have specified reachable and dexterous workspaces, see *McCarthy* and *Soh* [4.34].

4.5.2 Mechanical Advantage

The force amplification properties of a parallel robot are obtained by considering the Jacobians of the individual supporting chains. Let the linear and angular velocity of the platform be defined by the six-vector $\mathbf{v} = (\mathbf{v}, \boldsymbol{\omega})^T$, then from the kinematics equations of each of the support legs we have

$$\mathbf{v} = \mathbf{J}_1 \dot{\rho}_1 = \mathbf{J}_2 \dot{\rho}_2 = \cdots = \mathbf{J}_6 \dot{\rho}_6. \quad (4.15)$$

Here we assume that the platform is supported by six chains, but it can be fewer, such as when the fingers of a mechanical hand grasp an object [4.4].

The force on the platform applied by each chain is obtained from the principle of virtual work as

$$\mathbf{f}_j = (\mathbf{J}_j^T)^{-1} \boldsymbol{\tau}_j, \quad j = 1, \dots, 6. \quad (4.16)$$

There are only six actuated joints in the system so we assemble the associated joint torques into the vector $\boldsymbol{\tau} = (\tau_1, \dots, \tau_6)^T$. If \mathbf{f}_i is the force-torque vector obtained from (4.16) for $\tau_i = 1$ and the remaining torques to zero, then the resultant force-torque \mathbf{w} applied to the platform is

$$\mathbf{w} = (\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_6) \boldsymbol{\tau}, \quad (4.17)$$

or

$$\mathbf{w} = \boldsymbol{\Gamma} \boldsymbol{\tau}. \quad (4.18)$$

The elements of the coefficient matrix $\boldsymbol{\Gamma}$ define the mechanical advantage for each of the actuated joints. In the case of a Stewart platform the columns of this matrix are the Plücker coordinates of the lines along each leg [4.29].

The principle of virtual work yields the velocity of the platform in terms of the joints rates $\dot{\boldsymbol{\rho}}$ as

$$\boldsymbol{\Gamma}^T \mathbf{v} = \dot{\boldsymbol{\rho}}. \quad (4.19)$$

Fig. 4.10 One leg of the ASV walking machine is a parallel robot

Thus, the inverse of $\mathbf{\Gamma}$ defines the speed ratios between the actuated joints and the end-effector. The same equation can be obtained by computing the derivative of the geometric constraint equations (4.14), and $\mathbf{\Gamma}$ is the *Jacobian* of the parallel robot system [4.35].

The Jacobian $\mathbf{\Gamma}$ is used in parameter optimization algorithms to design parallel robots [4.36] with isotropic mechanical advantage. The square root of the determinant $|\mathbf{\Gamma}\mathbf{\Gamma}^T|$ measures the six-dimensional volume spanned by the column vectors \mathbf{f}_j . The distribution of the percentage of this volume compared to its maximum within the workspace is also used as a measure of the overall performance [4.37, 38]. A similar performance measure normalizes this Jacobian by

4.6 Mechanical Structure

For the purposes of dynamic modeling, the links of a robot are generally considered to be rigid. However, a robot is not a rigid structure. Like all structures it deflects under applied loads, such as its own weight and the weight of the payload, termed gravity loading; see Figs. 4.11 and 4.12. The issue is a matter of degree. The more force that is needed to cause a deflection in the links, the more the robot moves like a connected set of rigid bodies. Rigid robots have links designed to be stiff so the deflections under load are less than the positioning accuracy required for their range of tasks. This allows the dynamic model and control algorithms to ignore link deflection. Most commercially available robot arms are of this type (*Rivin* [4.44]).

It is possible to improve the positioning accuracy of a rigid robot by augmenting a control algorithm that includes a model of link deflection resulting from gravity loading. It is also possible to use strain sensors to measure loads and deflections. These *semirigid* robots assume small structural deflections that are linearly related to known applied loads.

Flexible robots require that the dynamic model include the deflection of its various links under gravity loading as well as under the forces associated with link acceleration, called inertia loading. The robot control algorithms must control the vibration of the system as well its gross motion. Management of vibration may be required even in rigid robots to reduce cycle time when subjected to high dynamic loading at high speeds or when manipulating large payloads.

4.6.1 Links

For industrial robots a critical concern is the link stiffness in bending and in torsion. To provide this stiffness, robot links are designed either as beams or shell (mono-

coque) structures. Monocoque structures have lower weight or higher strength-to-weight ratios, but are more costly and generally more difficult to manufacture. Cast, extruded, or machined beam-based links are often more cost effective; *Juvinall* and *Marshek* [4.45], and *Shigley* and *Mischke* [4.46, 47]

4.5.3 Specialized Parallel Robots

Another approach to the design of parallel robots has been to separate their functionality into orientation and translational platforms. *Tsai* and *Joshi* [4.40] and *Jin* and *Yang* [4.41] survey designs for a class of parallel chains that generate pure translation. *Kong* and *Gosselin* [4.42] and *Hess-Coelho* [4.43] do the same for parallel chains that provide rotational movement in space.

Another important consideration is whether the link structure includes bolted, welded, or adhesive bonded assemblies of cast, machined, and fabricated elements. Screw and bolted connections may seem straightforward, inexpensive, and easily maintained, but the inevitable deflection of a link even in the manufacturing process introduces creep in these multiple element assemblies that changes the dimensions and performance of the robot. Welded and cast structures are much less susceptible to creep and the associated hysteresis deformation, though in many cases they require secondary manufacturing operations such as thermal stress relieving and finish machining.

The minimum practical wall or web thickness for castings may be thicker than necessary for stiffness. Thin walls can be achieved with structural skin (mono-

Fig. 4.11 The hydraulic Skywash aircraft cleaning robot

Fig. 4.12 DeLaval Cow Milking System features hydraulic robot with machine vision guided positioning (VIDEO 643)

coque) structures but this is offset by the potential for denting, permanent deformation, and damage in the event of slight collisions. Therefore, both the performance and application requirements must be considered when selecting the construction and fabrication details of the robot.

4.7 Joint Mechanisms

A robot joint mechanism consists of at least four major components: the joint axis structure, an actuator, transmission, and state sensor (usually for position and velocity feedback, but force sensors are also common).

For low-performance manipulators that accelerate the payload at less than a peak of 0.5 g, system inertia is not as important as gravity forces and torques. This means the actuators can be placed near the joints, and their suspended weight compensated by using counterbalancing masses, springs, or gas pressure.

In high-performance robots where peak payload accelerations reach 3–10 g or more, minimizing system inertia is important. The actuators are placed near the first joint axis of a serial link manipulator to minimize its inertial contribution, and drive linkages, belts, cables or spaced gear stages are used to drive the joints.

While a longer transmission distance can reduce mass and gravity moments and inertia, it introduces

Performance- and application-specific materials and geometry are used to reduce the weight of the links and therefore the associated gravity and inertial loading. For structures that move in a straight line, aluminum or magnesium alloy extrusions of constant cross section are convenient. Carbon and glass-fiber composites provide lower mass for robots that require high acceleration (painting robots). Thermoplastic materials provide low-cost link structures though at reduced load capacity. Stainless steel is often used in robots for medical and food service applications. The longer links on serial chain robots often are designed to taper in cross section or wall thickness to reduce the associated inertial loading.

4.6.2 Joints

Joints for most robots allow either rotary or linear movement, termed revolute and prismatic joints. Other joints that are available are the ball-in-socket, or spherical joint, and the Hooke-type universal joint.

Integration of the mechanical structure of the robot with its joint mechanism, which includes the actuator and joint motion sensor, is a source of structural flexibility. Precision is reduced when deformation in the joint at its bearings can reduce gear and shaft preloads, allowing undesirable backlash and free play. Structural flexibility can also introduce changes in gear center spacing, introducing forces and torques and associated deflection, binding, jamming, and wear.

flexibility and thus reduces the system stiffness. The design of the actuator placement and transmission for each joint is a trade-off between weight, inertia, stiffness, and complexity. This choice dictates the major physical characteristics of a manipulator design. To illustrate this point, consider the Adept 1 assembly robot with four degrees of freedom, each a different structure. The first axis has a direct motor drive. The second axis is driven by a steel band drive, and the third by a synchronous belt drive. Finally, the fourth axis uses a linear ball-screw drive. For a variety of useful joint mechanisms *Sclater* and *Chironis* [4.48].

4.7.1 Joint Axis Structures

Revolute Joints

Revolute or rotary motion joints are designed to perform pure rotation while minimizing other displacements and motions. The most important measure of the

quality of a revolute joint is its stiffness or resistance to all undesired motion. Key factors to be considered in design for stiffness are shaft diameter, mounting configuration and preloading of the bearings and proper clearances and tolerances. Shaft diameter and bearing size are not always based on load-carrying capacity; rather, they often will be selected to be compatible with a rigid mounting configuration and also have a bore large enough to pass cables, hoses, and even drive elements for other joints. Because joint shafts will frequently be torque-transmitting members, they and their supporting structure must be designed both for bending and torsional stiffness. The first axis of the PUMA robot is an example of such a joint with its large-diameter tubular configuration.

An important factor in maintaining stiffness in a revolute joint is the choice of bearing-mounting configuration. The mounting arrangement and mount must be designed to accommodate manufacturing tolerances, thermal expansion and bearing preload. Axial preloading of ball or tapered roller bearings improves system accuracy and stiffness by minimizing both axial and radial play. Preloads can be achieved through selective assembly or elastic (spring) elements, shim spacers, threaded collars, four-point contact bearings, duplex bearing arrangements, and tight manufacturing tolerances.

Prismatic Joints

There are two basic types of prismatic or linear motion joints: single-stage and telescoping joints. Often a prismatic joint and its associated link and actuator are combined as a linear actuator. Single-stage joints are made up of a moving surface that slides linearly along a fixed surface. Telescoping joints are essentially sets of nested or stacked single-stage joints. Single-stage joints feature simplicity and high stiffness, whereas the primary advantage of telescoping joints is their retracted-state compactness and large extension ratio. Telescoping joints have a lower effective joint inertia for some configurations and motions because part of the joint may remain stationary or move with reduced acceleration.

The primary functions of bearings in prismatic joints are to facilitate motion in a single direction and to prevent motion in all other directions. Preventing these unwanted motions poses the more challenging design problem. Deformations in the structure can distort the bearing. In severe cases, ball or roller deflection under load may cause binding, which precludes motion. For high-precision prismatic joints, ways must be straight and precise along their entire length which may be several meters. The required precision grinding on multiple surfaces can be costly. Bulky covers may be required to shield and seal a prismatic bearing and way assembly.

The primary criterion for evaluating higher number (in or near the wrist or end-effector) linear motion joints or axes is the stiffness-to-weight ratio. Achieving a good stiffness-to-weight ratio requires the use of a hollow or thin-walled structure rather than solid members for the moving elements.

Bearing spacing is extremely important in design for stiffness. If this spacing is too short, system stiffness will be inadequate no matter how great the bearing stiffness. A major cause for failure in prismatic joints is surface fatigue wear (brinelling) of the ways caused by excessive ball loading due to high preload, moment loads and shock loads.

The large exposed precision surfaces in most prismatic joints make them much more sensitive than revolute joints to contamination, improper handling and environmental effects. They are also significantly more difficult to manufacture, properly assemble, and align.

Common types of sliding elements for prismatic motion are bronze or thermoplastic impregnated bushings. These bushings have the advantage of being low in cost, of having relatively high load capacity, and of working with unhardened or superficially hardened (i.e., plated or anodized) surfaces. Because the local or contact stress on the moving element is distributed and is low this element may be made of thin tube or an extruded shape. Another type of bushing in common use is the ball bushing. Ball bushings have the advantages of lower friction and greater precision than plain bushings. However, they require that the contacting surface of the joint be heat treated or hardened (generally to Rc 55 or greater) and of sufficient case and wall thickness to support the ball point contact loads and resulting high stresses.

Ball and roller slide assemblies are commonly used in robot prismatic joints. There are two basic categories of these slides; recirculating and non-recirculating. Non-recirculating ball and roller slides are used primarily for short-travel applications. They feature high precision and very low friction at the expense of being more sensitive to shock and relatively poor at accommodating moment loading. Recirculating ball slides are somewhat less precise but can carry higher loads than non-recirculating ball slides. They can also be set up to handle relatively large moment loads. Travel range can be up to several meters. Commercial recirculating ball slides and ways have greatly simplified the design and construction of linear axes, particularly in gantry and track mounted manipulators.

Another common type of prismatic robot joint is made up of cam followers, rollers, or wheels rolling on extruded, drawn, machined, or ground surfaces. In high-load applications the surfaces must be hardened before they are finish ground. Cam followers can be purchased

Fig. 4.13 RobotWorld is an integrated workcell with multiple robot modules that move on air bearings

with eccentric mounting shafts to facilitate setup and adjustment. Elastomer rollers provide quiet, smooth operation.

Two less common types of linear or prismatic joints feature flexures and air bearings. Flexure-based joints, whose motion results from elastic bending deformations of beam support elements, are used primarily for small, high-resolution, quasilinear motions. Air bearings require smooth surfaces and close control of tolerances as well as a constant supply of filtered, oil-free compressed air. Two- and three-degree-of-freedom air bearings (x, y, θ) can enable multiaxis motion with few moving parts (Fig. 4.13).

Joint Travel

For revolute joint configurations, the shoulder and elbow joints and links determine the gross volume of the work envelope (reachable workspace) of a robot manipulator arm. The wrist joints generally determine the orientation range (dexterous workspace) about a point within this work envelope. Larger joint travel may increase the number of possible manipulator configurations that will reach a particular location (increased task space). Wrist joint travel in excess of 360° and up to

Fig. 4.14 Wrist for surgery has no singularities within range of motion. Features tungsten cable actuation (after [4.49])

720° can be useful for situations requiring controlled-path (e.g., straight-line) motion, synchronized motion such as small part assembly on a moving conveyor belt, or sensor-modified motions as in using machine vision to select and guide picking jumbled items from a bin. Continuous last-joint rotation is desirable in certain cases like loading or unloading a rotating machine or mating threaded parts.

Additional joints and links, sometimes in the robot but more often in the end-effector, and specialized tooling also serve to increase the task space of a robot. Continuous and controlled-path robot motion requires planning to avoid singularities (regions where two or more joints may become aligned or nearly aligned) and the resulting unstable end-effector motion in these regions. Manipulator design coordinated with a well-planned workcell layout can improve the useful task space by placing critical motions well away from singularity regions. For example, a standard three-axis robot wrist has singularities 180° apart, which can be increased to 360° by implementing a somewhat more complex reduced singularity wrist. Such a wrist is used in a sheep-shearing robot to achieve multiple, long, continuous, smooth, constant-velocity, sensor-guided passes over the contoured body of a sheep to shear its wool [4.50, 51]. Figure 4.14 shows a wrist used for minimally-invasive surgery that has no singularities within its range of motion [4.49].

4.8 Actuators

Actuators supply the motive power for robots. Most robot actuators are commercially available components, which are adapted or modified, as necessary, for a specific robot application. Three commonly used actuator types are electromagnetic, hydraulic and pneumatic.

4.8.1 Electromagnetic Actuators

The most common types of actuators in robots today are electromagnetic actuators.

Electric Servomotors

Most robot manipulators use servomotors as a power source. Servomotors are designed to accurately follow the desired position, velocity and torque which change frequently and sometimes abruptly. They have structures similar to ordinary electric motors, but with low inertia and large torque capably for high accelerations. Typical servomotors used for robotic applications are permanent magnet (PM) DC motors and brushless DC (BLDC) motors.

PM DC motors are widely used as a servomotor because of high torque, speed controllability over a wide range, well-behaved torque-speed characteristics, and adaptability to various types of control methods. The **DC** motor converts electrical energy into rotational or linear mechanical energy. It comes in many different types and configurations. The lowest-cost **PM** motors use ceramic (ferrite) magnets and robot toys and hobby robots often use this type of motor. A **PM** motor with a rare-earth (neodymium-iron-boron), **NEO** magnet stator produces the most torque and power for its size.

Brushless motors, also called **AC** servomotors or brushless **DC** motors, are widely used in industrial robots (Figs. 4.15 and 4.16). They substitute magnetic or optical sensors and electronic switching circuitry for the graphite brushes and copper bar commutator used in brush-type **DC** motors, thus eliminating the friction, spark-ing, and wear of commutating parts. Brushless motors generally have good performance at low cost because of the decreased complexity of the motor. However, the controllers for these motors are more complex and expensive than brush-type motor controllers. A passive multi-pole neodymium magnet rotor and a wire-wound iron stator of a brushless motor provide good heat dissipation and excellent reliability. Linear brushless motors function like unrolled rotary motors. They typically have a long, heavy, multiple

Fig. 4.15 The Baldor **AC** servomotor

Fig. 4.16 The Anorad brushless linear motor

magnet passive stator and a short, lightweight, electronically commutated wire-wound forcer (slider).

Modeling of DC Motors and BLDC Motors. Both **DC** and **BLDC** motors can be described by almost identical equations although they have different structures, *de Silva* [4.52]. Fig. 4.17. The motor torque τ_m generated at the motor is given by,

$$\tau_m = K_t i_a, \quad (4.20)$$

where K_t is the torque constant [N m/A] and i_a is the armature current [A].

When the rotor is rotating, the back electromotive force (**emf**) v_b is induced as follows,

$$v_b = K_b \omega_m, \quad (4.21)$$

where K_b is the back **emf** constant [V/(rad/s)] and ω_m is the angular speed of the motor [rad/s].

The circuit equation is given by

$$v_a = R_a i_a + L_a \frac{di_a}{dt} + v_b, \quad (4.22)$$

where v_a is the armature voltage (supply voltage to the armature) [V], R_a and L_a are the resistance [Ω] and inductance [H] of the armature winding, respectively.

Lastly, the mechanical equation is described by

$$J \frac{d\omega_m}{dt} + B \omega_m = \tau_m - \frac{\tau_l}{r}, \quad (4.23)$$

where J is the equivalent moment of inertia referred to the motor shaft [kg m^2], B is the equivalent viscous-friction coefficient referred to the motor shaft [N m/rad/s], τ_l is the load torque [N m], and r is the gear ratio. The quantities J and B are given by

$$J = J_m + \frac{J_l}{r^2}, \quad B = B_m + \frac{B_l}{r^2}, \quad (4.24)$$

where J_m and B_m are related to the motor including the gear connected to the motor shaft and J_l and B_l are referred to the load including the gear connected to the load shaft.

Fig. 4.17 Servomotor models

The four equations above can be represented as the block diagram in Fig. 4.18.

In the servomotors, the electrical time constant $\tau_e = L_a/R_a$ and mechanical time constant $\tau_m = J/B$ have effects on their performance. The electrical time constant is much smaller than mechanical time constant because of the armature inductance is usually negligible. Considering this factor, the angular speed of the motor is described in terms of the armature voltage v_a and load torque τ_l as follows

$$\omega_m(s) = \frac{1}{JR_a s + (R_a B + K_t K_b)} \left(K_t v_a(s) - R_a \frac{\tau_l(s)}{r} \right). \quad (4.25)$$

The above equation is frequently used in simulations of both DC motor and BLDC motors.

Stepper Motors. Small, simple robots, such as bench-top adhesive dispensing robots, frequently use stepper or pulse motors of the permanent magnet (PM) hybrid type or sometimes the variable reluctance (VR) type (Fig. 4.19). These robots use open-loop position and velocity control. They are relatively low in cost and interface easily to electronic drive circuits. Microstep control can produce 10 000 or more discrete robot joint positions. In open-loop step mode the motors and robot motions have a significant settling time, which can be

Fig. 4.18 Block diagram for servomotors

Fig. 4.19 The Sony robot uses open-loop permanent-magnet stepper motors

damped either mechanically or through the application of control algorithms. Power-to-weight ratios are lower for stepper motors than for other types of electric motors. Stepper motors operated with closed-loop control function similarly to direct-current (DC) or alternating-current (AC) servomotors (Fig. 4.20).

Permanent-Magnet DC Motor. The permanent-magnet, direct-current, brush-commutated motor is widely available and comes in many different types and configurations. The lowest-cost permanent-magnet motors use ceramic (ferrite) magnets. Robot toys and hobby robots often use this type of motor. Neodymium (NEO) magnet motors have the highest energy-product magnets, and in general produce the most torque and power for their size.

Ironless rotor motors, often used in small robots, typically have copper wire conductors molded into epoxy or composite cup or disk rotor structures. The advantages of these motors include low inductance, low friction, and no cogging torque. Disk armature motors have several advantages. They have short overall lengths, and because their rotors have many commutation segments, they produce a smooth output with low torque ripple. A disadvantage of ironless armature motors is that they have a low thermal capacity due to low mass and limited thermal paths to their case. As a result, when driven at high power levels they have rigid duty-cycle limitations or require forced-air cooling.

4.8.2 Hydraulic Actuators

Hydraulic actuators, chosen as power sources for the earliest industrial robots, offer very large force capability and high power-to-weight ratios. They convert hydraulic power into useful mechanical energy. The mechanical motion produced may be linear for hy-

Fig. 4.20 The Adept robot uses closed-loop control and variable-reluctance motors (VIDEO 644)

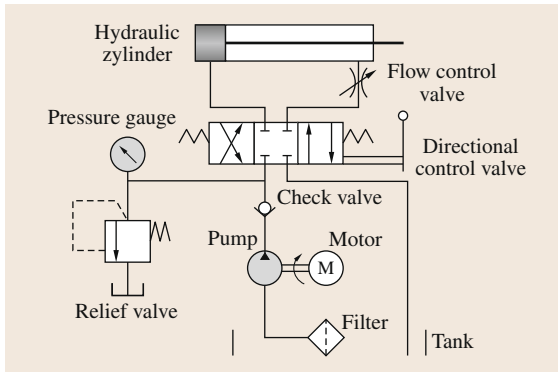

Fig. 4.21 General hydraulic circuit

hydraulic cylinders or rotary for hydraulic motors and vane actuators.

Figure 4.21 shows the basic hydraulic circuit composed of oil tank, hydraulic pump, check valve, relief valve, directional control valve and hydraulic actuator. Hydraulic fluid pressurized by the hydraulic pump is conveyed to the hydraulic machine to perform the specified task. To this end, the pressure, flow, and direction of hydraulic fluid is changed by the hydraulic control valves such as a pressure control valve, flow control valve, and directional control valve, respectively. The directional control valve changes the flow direction of the hydraulic fluid which is pressurized in the hydraulic pump and thus the direction of actuator motion. The flow control valve changes the flow rate of hydraulic fluid flow and thus the speed of the hydraulic actuator. For safety, the highest pressure is limited by the pressure control valve such as a relief valve.

Hydraulic actuators have several advantages and disadvantages due to the use of high pressure fluid. They can offer very large force or torque and high power-to-weight ratios. Both linear and rotary motions are readily available with small inertia of the moving part. However, the hydraulic power supply is bulky and the cost of the proportional, fast-response servovalves are high. Leaks and maintenance issues have limited the use and application of hydraulically powered robots.

There have been many applications of hydraulic actuators to robotics. For high forces or torques and speeds, hydraulic servo actuators out-perform current electromagnetic actuators. With proper design, leakage can be virtually eliminated, *Hollerbach et al.* [4.53]. Figure 4.22 shows some typical applications of hydraulic actuators, [4.54–56].

4.8.3 Pneumatic Actuators

Pneumatic actuators are similar to hydraulic actuators. Pneumatic actuators convert energy (in the form of compressed air) into mechanical motion, which may be linear or rotary. Pneumatic actuators are primarily found in simple manipulators. Typically they provide uncontrolled motion between mechanical limit stops. These actuators provide good performance in point-to-point motion. They are simple to control and are low in cost. Pneumatic motors have several advantages over electric motors. They are relatively safe in the explosive environment. They are also less affected by ambient temperature and humidity than electric motors. Although a few small actuators may be run with typical factory air supplies, extensive use of pneumatic-actuated robots requires the purchase and installation of a costly dedicated compressed-air source. Pneumatic actuators have low energy efficiency.

Pneumatic systems consist of pneumatic generator, pneumatic valves, pneumatic actuator and pipes. A pneumatic generator produces compressed air using an air compressor. Pneumatic valves are used to control the pressure, flow rate and direction. The mechanical motion produced may be linear for pneumatic cylinders or rotary for pneumatic motors.

Pneumatic actuators are not used for applications requiring large forces or torques since they produce less power than hydraulic actuators or electric actuators. However, they are used in robot hands or artificial muscles, which require high power-to-weight ratios. Pneumatic artificial muscles are contractile or extensional devices operated by pressurized air filling a pneumatic bladder. They are usually grouped in the agonist

Fig. 4.22a–c Applications of hydraulic actuators to robot: (a) BigDog (Boston dynamics) (VIDEO 645), (b) Sarcos exoskeleton (VIDEO 646) (Raytheon) (c) Magnum 7 (International Submarine Engineering)

Fig. 4.23a,b Applications of pneumatic actuator: (a) robot hand and arm with artificial muscle (Shadow robot) and (b) pneumatic step motor and MrBot (Urobotics, Johns Hopkins)

and antagonist pairs. Furthermore, they can be used for medical robots since they are not affected by magnetic field, and for robots in explosive environments because there is no electrical arcing that exists in electromagnetic actuators. Figure 4.23 shows some robotic applications of pneumatic actuators [4.57, 58].

4.8.4 Other Actuators

A wide variety of other types of actuators have been applied to robots. A sampling of these include, thermal, shape-memory alloy (SMA), bimetallic, chemical, piezoelectric, magnetostrictive, electroactive polymer (EAP), bladder, and micro-electromechanical system (MEMS) actuators (see Figs. 4.24 and 4.25). Most of these actuators have been applied to research and special application robots rather than volume production industrial robots. An example of a piezoelectric actuator powered robot is the six-axis PI (Physik Instrumente) piezo hexapod with sub-nanometer resolution shown in Fig. 4.26.

Fig. 4.24 The artificial muscle EAP motor

Fig. 4.25 The Elliptec piezoelectric motor

4.8.5 Transmissions

The purpose of a transmission or drive mechanism is to transfer mechanical power from a source to a load. The design and selection of a robot drive mechanism requires consideration of motion, load, and power requirements and the placement of the actuator with respect to the joint. The primary considerations in transmission design are stiffness, efficiency, and cost. Backlash and windup impact drive stiffness especially in robot applications where motion is constantly reversing and loading is highly variable. High transmission stiffness and low or no backlash result in increased friction losses. Most robot transmission elements have good efficiencies when they are operating at or near their rated power levels but not necessarily when lightly loaded. Larger than necessary drives add weight, inertia and friction loss to the system. Underdesigned drives have lower stiffness, can wear rapidly in continuous or in high duty cycle operation or fail due to accidental overloads.

Joint actuation in robots is generally performed by drive mechanisms which interface the actuator (mechanical work source) to the robot links through the joints in an energy-efficient manner. A variety of drive mechanisms are incorporated in practical robots. The transmission ratio of the drive mechanism sets the torque, speed, and inertia relationship of the actuator to the link. Proper placement, sizing, and design of the drive mechanisms set the stiffness, mass, and overall operational performance of the robot. Most modern robots incorporate efficient, overload damage resistant, back-driveable drives.

Fig. 4.26 A six-axis Physik Instrumente (PI) piezo hexapod with sub-nanometer resolution (VIDEO 648)

Direct Drives

The direct drive is kinematically the simplest drive mechanism. In the case of pneumatic or hydraulic actuated robots, the actuator is directly connected between the links. Electric direct-drive robots employ high-torque, low-speed rotary or linear motors directly interfaced to the links. The complete elimination of free play and smooth torque transmission are features of a direct drive. However, there is often a poor dynamic (inertia ratio) match of the actuator to the link requiring a larger, less energy efficient, actuator.

Band Drives

A variant of direct drive is band drive. A thin alloy steel or titanium band is fixed between the actuator shaft and the driven link to produce limited rotary or linear motion. Drive ratios in the order of up to 10 : 1 (10 actuator revolutions for 1 revolution of the joint) can be obtained. Actuator mass is also moved away from the joint – usually toward the base, to reduce robot inertia and gravity loading. It is a smoother and generally stiffer drive than a cable or belt drive.

Belt Drives

Synchronous (toothed) belts are often employed in drive mechanisms of smaller robots and some axes of larger robots. These function much the same as band drives, but have the ability to drive continuously. Multiple stages (two or three) are occasionally used to produce large drive ratios (up to 100 : 1). Belt tension is controlled with idlers or center adjustment. The elasticity and mass of long belts can cause drive instability and thus increased robot settling time.

Gear Drives

Spur or helical gear drives provide reliable, sealed, low-maintenance power transmission in robots. They are used in robot wrists where multiple axes intersect and compact drive arrangements are required. Large-diameter gears are used in the base joints of larger robots to handle high torques with high stiffness. Gears are often used in stages and often with long drive shafts, enabling large physical separation between actuator and driven joint. For example, the actuator and one stage of reduction may be located near the elbow driving another stage of gearing or differential in a wrist through a long hollow drive shaft (Fig. 4.1).

Planetary gear drives are often integrated into compact gearmotors (Fig. 4.27). Minimizing backlash (free play) in a joint gear drive requires careful design, high-precision and rigid support to produce a drive mechanism which does not sacrifice stiffness, efficiency and accuracy for low backlash. Backlash in robots is

controlled by a number of methods including selective assembly, gear center adjustment, and proprietary anti-backlash designs.

Worm Gear Drives

Worm gear drives are occasionally used in low-speed robot manipulator applications. They feature right-angle and offset drive capability, high ratios, simplicity, good stiffness and load capacity. They have poor efficiency, which makes them non-back-driveable at high ratios. This causes the joints to hold their position when unpowered but also makes them prone to damage by attempts to manually reposition the robot.

Proprietary Drives

Proprietary drives are widely used in standard industrial manipulators. The harmonic drive and the rotary vector (RV) drive are two examples of compact, low-backlash, high-torque-capability drives using special gears, cams, and bearings (Figs. 4.28 and 4.29).

Harmonic drives are frequently used in very small to medium-sized robots. These drives have low backlash, but its flexspline allows elastic windup and low stiffness during small reversing movements. RV drives are

Fig. 4.27 The Space Shuttle robot arm has planetary gear joint drives

Fig. 4.28 The harmonic drive (VIDEO 649)

usually used in larger robots, especially those subject to overloads and shock loading.

Linear Drives

Direct-drive linear actuators incorporate a linear motor with a linkage to a linear axis. This linkage is often merely a rigid or flexure connection between the actuator forcer and the robot link. Alternatively, a packaged linear motor with its own guideways is mechanically connected directly to a linear axis. Direct linear electromagnetic drives feature zero backlash, high stiffness, high speeds, and excellent performance but are heavy, have poor energy efficiency, and cost more than other types of linear drives.

Ball Screws

Ball-screw-based linear drives efficiently and smoothly convert rotary actuator motion into linear motion. Typically, a recirculating ball nut mates with a ground and hardened alloy steel screw to convert rotary motion into linear motion. Ball screws can be easily integrated into linear axes. Compact actuator/drive packages are available, as well as components for custom integration. Stiffness is good for short and medium travel, however it is lower for long motions because the screw can only be supported at its ends. Low or zero backlash can be obtained with precision-ground screws. Speeds are lim-

ited by screw dynamic stability so rotating nuts enable higher speeds. Low-cost robots may employ plain screw drives featuring thermoplastic nuts on smooth rolled thread screws.

Rack-and-Pinion Drives

These traditional components are useful for long motions where the guideways are straight or even curved. Stiffness is determined by the gear/rack interface and independent of length of travel. Backlash can be diffi-

Fig. 4.31 Two-arm collaborative robot with Series Elastic Actuators (after [4.59])

Fig. 4.29 The Nabtesco RV drive

Fig. 4.30 The NASA gantry robot

Fig. 4.32 Series Elastic Actuator assembly in knee-ankle-foot gait rehabilitation robot (after [4.60])

cult to control as rack-to-pinion center tolerances must be held over the entire length of travel. Dual pinion drives are sometimes employed to deal with backlash by providing active preload. Forces are generally lower than with screws due to lower ratios. Small-diameter (low teeth count) pinions have poor contact ratios, resulting in vibration. Sliding involute tooth contact requires lubrication to minimize wear. These catalog stock drive components are often used on large gantry robots and track-mounted manipulators (Fig. 4.30).

Compliant Actuators. Compliance in the form of elasticity in a drive can be an asset or a defect in a robot. High overall robot stiffness traditionally produces fast response, high positioning accuracy and simplified control. However the contact and interaction forces developed due to unexpected errors in dealing with the workpieces, tools, workplace and the environment can cause damage to the robot, the surroundings, and injury to persons. By adding controlled and measureable compliance to actuators, the elasticity of the robot can be usefully increased.

One class of reduced stiffness actuator is the Series Elastic Actuator (SEA). It features an elastic output element (spring) with a displacement sensor (measures

spring stretch) in series with a stiff actuator and transmission component. With an appropriate controller, the stiff classical position control actuator acts as a force actuator ($F = -kx$), effectively isolating the drive inertia from the load inertia. This limits the forces resulting from collisions or forced compliance often encountered when working in unstructured environments and around persons. SEAs and similar compliant actuators and compliant actuator configurations are discussed in Chap. 69. Collaborative robots are designed to safely work next to or in contact with persons, Fig. 4.31 [4.59], and are an example of robots featuring compliant actuators. Figure 4.32 shows compliant actuators used in an exoskeleton for gait rehabilitation [4.60].

Other Drive Components

Splined shafts, kinematic linkages (four-bar, slider-crank mechanisms, etc.) chains, cables, flex couplings, clutches, brakes, and limit stops are some examples of other mechanical components used in robot drive mechanisms (Fig. 4.8). The Yaskawa RobotWorld assembly and process automation robot system features a magnetically suspended direct electromagnetic drive planar (2 axis) motor with no internal moving parts floating on a virtually frictionless planar air bearing. (Fig. 4.12).

4.9 Robot Performance

Industrial robot performance is often specified in terms of functional operations and cycle time. For assembly robots the specification is often the number of typical pick-and-place cycles per minute. Arc-welding robots are specified with a slow weld pattern and weave speed as well as by a fast repositioning speed. For painting robots, the deposition or coverage rate and spray pattern speed are important. Peak robot velocity and acceleration catalog data are generally just calculated numbers and will vary due to dynamic (inertia) and static (gravity) coupling between robot joints due to configuration changes as a robot moves.

4.9.1 Robot Speed

Maximum joint velocity (angular or linear) is not an independent value. For longer motions it is often limited by servomotor bus voltage or maximum allowable motor speed. For manipulators with high accelerations, even short point-to-point motions may be velocity limited. For low-acceleration robots, only gross motions will be velocity limited. Typical peak end-effector speeds can range up to 20 m/s for large or fast manipulators.

4.9.2 Robot Acceleration

In most modern manipulators, because the payload mass is small when compared with the manipulator mass, more power is spent accelerating the manipulator than the load. Acceleration affects gross motion time as well as cycle time (gross motion time plus settling time). Manipulators capable of greater acceleration tend to be stiffer manipulators. In high-performance robot manipulators, acceleration and settling time are more important design parameters than velocity or load capacity. Maximum acceleration for some assembly and material handling robots is in excess of 10 g with light payloads.

4.9.3 Repeatability

This specification represents the ability of the manipulator to return repeatedly to the same location. Depending on the method of teaching or programming the manipulator, most manufacturers intend this figure to indicate the radius of a sphere enclosing the set of locations to which the arm returns when sent from the same origin by the same program with the

same load and setup conditions. This sphere may not include the target point because calculation round-off errors, simplified calibration, precision limitations, and differences during the teaching and execution modes can cause significantly larger errors than those just due to friction, unresolved joint and drive backlash, servo system gain, and structural and mechanical assembly clearances and play. The designer must seriously consider the real meaning of the required repeatability specification. Repeatability is important when performing repetitive tasks such as blind assembly or machine loading. Typical repeatability specifications range from 1–2 mm for large spot-welding robots to 0.005 mm (5 μ m) for precise micropositioning manipulators.

4.9.4 Resolution

This specification represents the smallest incremental motion that can be produced by the manipulator. Resolution is important in sensor-controlled robot motion and in fine positioning. Although most manufacturers calculate system resolution from the resolution of the joint position encoders, or from servomotor and drive step size, this calculation is misleading because system friction, windup, backlash, and kinematic configuration affect the system resolution. Typical encoder or resolver resolution is 10^{14} – 10^{25} counts for full-axis or joint travel, but actual physical resolution may be in the range 0.001–0.5 mm. The useful resolution of a multi-joint serial-link manipulator is worse than that of its individual joints.

4.9.5 Accuracy

This specification covers the ability of a robot to position its end-effector at a preprogrammed location in space. Robot accuracy is important in the performance of nonrepetitive types of tasks programmed from a database, or for taught tasks that have been remapped or offset owing to measured changes in the installation.

Accuracy is a function of the precision of the arm kinematic model (joint type, link lengths, angles between joints, any accounting for link or joint deflections under load, etc.), the precision of the world, tool, and fixture models, and the completeness and accuracy of the arm solution routine. Although most higher-level robot programming languages support arm solutions, these solutions usually model only simplified rigid-body kinematic configurations. Thus, manipulator accuracy becomes a matter of matching the robot geometry to the robot solution in use by precisely measuring and calibrating link lengths, joint angles, and mounting positions.

Typical accuracies for industrial manipulators range from ± 10 mm for uncalibrated manipulators that have poor computer models to ± 0.01 mm for machine-tool-like manipulators that have controllers with accurate kinematic models and solutions and precisely manufactured and measured kinematic elements.

4.9.6 Component Life and Duty Cycle

The three subassemblies in an electrically powered robot with the greatest failure problems are the actuators (servomotors), transmissions, and power and signal cables. Mean time between failures (MTBF) should be a minimum of 5000 h on line, and ideally at least 10 000 operating hours should pass between major component preventive maintenance replacement schedules.

Worst-case motion cycles must be assumed as most current robot installations are used in generally repetitive tasks. Small-motion design-cycle life (less than 5% of joint travel range) for assembly robots should be 20–100 million full bidirectional cycles. Large-motion cycle life (greater than 50% of full joint range) should typically be 5–40 million cycles.

Short-term peak performance is frequently limited by maximum drive loading, whereas long-term, continuous, performance is limited by motor heating. Rather than design for equal levels of short- and long-term performance, cost savings and performance improvements can result from designing for an anticipated duty cycle. This allows the use of smaller, lower-inertia, lighter motors. Industrial robots usually become obsolete and are replaced before they reach their design cycle life.

4.9.7 Collisions

In the course of operation, unforeseen or unexpected situations may occasionally result in a collision involving the manipulator, its tools, the workpiece, or other objects in the workplace. These accidents may result in no, little, or extensive damage, depending in large part on the design of the manipulator. Crash-resistant design options should be considered early in the design process if the time lost or cost of such accidents could be significant. Typical damage due to accidents include fracture or shear failures of gear teeth or shafts, dented or bent link structures, slipping of gears or pulleys on shafts, cut or severely abraded or deformed wires, cables or hoses, and broken connectors, fittings, limit stops or switches. Compliant elements such as overload (slip) clutches, elastic members, and padded surfaces can be incorporated to reduce shock loads and help decouple or isolate the actuators and drive components in the event of such collisions.

4.10 Conclusions and Further Reading

The mechanical design of a robot is an iterative process involving engineering, technical, and application-specific considerations evaluations, and choices. The final design should reflect consideration of detailed task requirements rather than simply broad specifications. Proper identification and understanding of these requirements is a key to achieving the design goals.

Design and choice of specific components involves tradeoffs. A purely static, rigid-body approach to manipulator design is often used, but is not always sufficient. Mechanical system stiffness, natural frequencies, control system compatibility, and intended robot applications and installation requirements must be considered.

There are many opportunities for further reading on the design of the mechanisms and actuation that form the core of a robotic system. A well-known and useful reference for robot design is *Rivin* [4.44].

Craig [4.6] and *Tsai* [4.9] provide the mathematical relations between the mechanical structure of a robot and its workspace and mechanical advantage. *Sclater* and *Chironis* [4.48] is a reprint of a valuable compendium of devices useful for a variety of applications, such as joint drives and transmissions. See *McCarthy* and *Soh* [4.34] for geometric techniques to design specialized mechanisms.

Juvinall and *Marshek* [4.45] and *Shigley* and *Mischke* [4.46, 47] are important references for the design of the components such as the link structure, bearings, and transmissions that are central to the effective mechanical performance of robotic systems.

Although many design decisions can be made through the application of straightforward algorithms and equations, a multitude of other important considerations transform the challenge of robot design into one requiring good engineering judgment.

Sensing and estimation are essential aspects of the design of any robotic system. At a very basic level, the state of the robot itself must be estimated for feedback control. At a higher level, perception, which is defined here to be task-oriented interpretation of sensor data, allows the integration of sensor information across space and time to facilitate planning.

This chapter provides a brief overview of common sensing methods and estimation techniques that have found broad applicability in robotics. The presentation is structured according to a process model that includes sensing, feature extraction, data association, parameter estimation, and model integration. Several common sensing modalities are introduced and characterized. Common methods for estimation in linear and nonlinear systems are discussed, including statistical estimation, the Kalman filter, and sample-based methods. Strategies for robust estimation are also briefly described. Finally, several

common representations for estimation are introduced.

5.1 Introduction

Controlling a robotic system would be relatively simple if a complete model of the environment was available, and if the robot actuators could execute motion commands perfectly relative to this model. Unfortunately, in most cases of interest, a complete world model is not available, and perfect control of mechanical structures is never a realistic assumption. Sensing and estimation are a means of compensating for this lack of complete information. Their role is to provide information about the state of the environment and the state of the robot system as a basis for control, decision making, and interaction with other agents in the environment, such as humans.

For the purposes of discussion, we will differentiate between sensing and estimation to recover the state of the robot itself, referred to as *proprioception*, versus sensing and estimation to recover the state of the external world, referred to as *exteroception*. In practice, most robot systems are designed to have the proprioception necessary to estimate and control their own physical state. On the other hand, recovering the state of the world from sensor data is usually a much larger and more complex problem.

Early work on computational perception for robotics assumed that one could recover a complete general-purpose model of the environment, use such

a model to make decisions, and subsequently act on them, as for example presented by [5.1]. More recently it has become apparent that such an approach is not realistic. Indeed, considering that sensor-based robots now appear in diverse applications such as mobile surveillance, high-performance manipulation, and medical interventions, it is clear that appropriate sensing and estimation for a given system must be highly task dependent. Consequently, the discussion here is organized along the lines of task-oriented sensing and estimation of the external world.

Sensing and estimation together can be viewed as the process of transforming a physical quantity into a computer representation that can be used for further processing. Sensing is thus closely tied to transducers that transform some physical entity into a signal that can be processed by a computer. Sensing is also intimately tied to perception, the process of representing the sensory information in an task-oriented model of the world. However, sensor data is usually corrupted in var-

ious ways that complicate this process. Statistical noise arises from the transducer, discretization is introduced in the digitization process, and ambiguity is introduced by poor sensor selectivity to name a few examples. Estimation methods are thus introduced to support appropriate integration of information into models of the environment and for improvement of the signal-to-noise ratio.

In this chapter the general characteristics of sensing and estimation are introduced, while more in-depth presentations of select topics are provided in Part C of the handbook. In Sect. 5.2 the overall sensing/perception process is introduced. In Sect. 5.3 different kinds of sensors are introduced and some key characteristics are presented. Estimation of world representations can utilize a number of different methods involving both parametric and nonparametric techniques as discussed in Sect. 5.4. For model-based integration a variety of different representations can be used, as described in Sect. 5.5.

5.2 The Perception Process

The input to the perception process is typically twofold: (1) digital data from a number of sensors/transducers, and (2) a partial model of the environment (a world model) that includes information about the state of the robot and other relevant entities in the external world. The sensor data itself can take on a number of different forms such as a scalar or vector value $x(\alpha, \beta)$ acquired over a time series $x(t)$, a scan $x_r(\theta_i)$, a vector field \mathbf{x} or a three-dimensional volume $x(\rho, \theta, \phi)$. In many cases, a system must integrate data from several disparate sensors, for example, an estimate of the position of a mobile robot may integrate data from axis encoders, vision, global positioning system (GPS) data, and inertial sensors.

To further structure the discussion in this chapter, we adopt a general model of the perception process

as shown in Fig. 5.1. In this model, we have included the most common operations applied to integrate sensor data with a world model. Depending on the task in question, some of the included modules may be missing, and others may themselves take on a complicated structure. However, the supplied model suffices to illustrate many of the issues in sensing and estimation. In the remainder of this section, we discuss an example from mobile localization to illustrate this model.

The initial problem in sensory processing is data preprocessing and feature extraction. The role of preprocessing is to reduce noise from the transducer, to remove any systematic errors, and to enhance relevant aspects of the data. In some cases, sensory information might also have to be temporally or spatially aligned for subsequent integration. There are innumerable ways

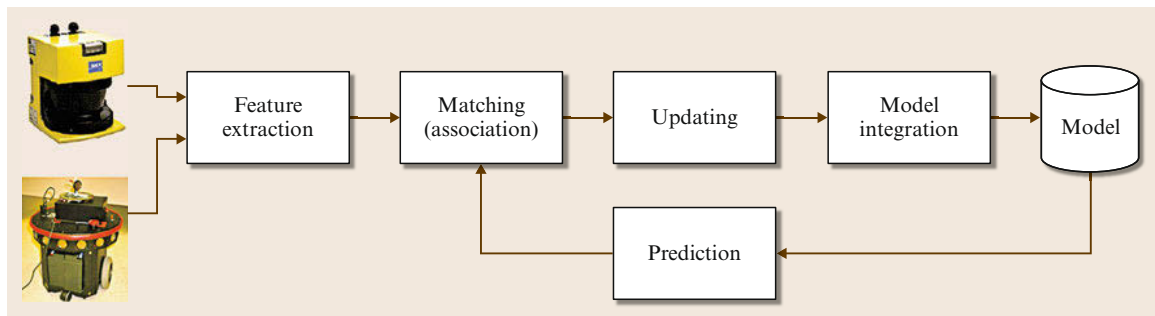

Fig. 5.1 Example of a perception process as discussed in this chapter

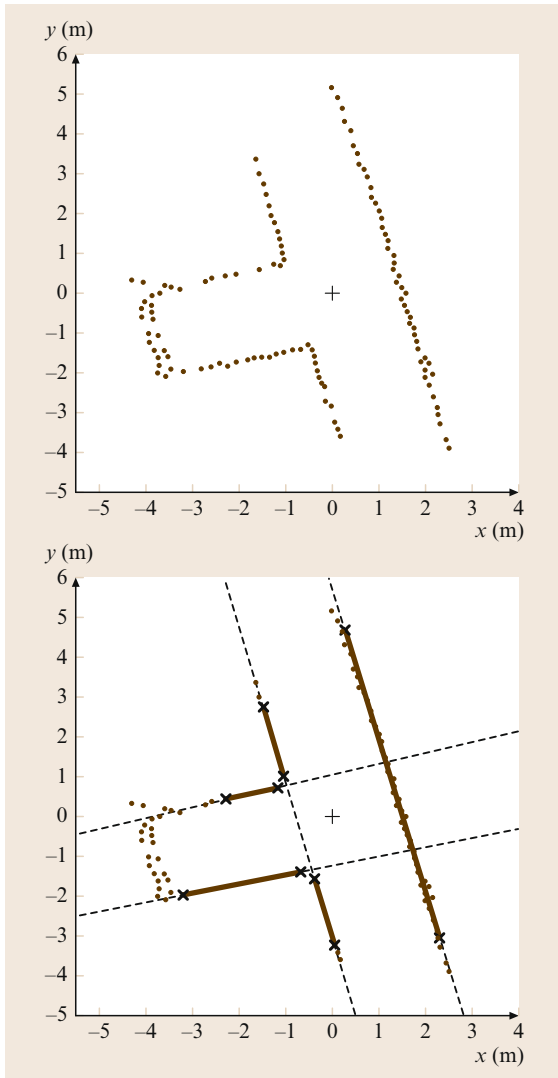

Fig. 5.2 An example of feature extraction from a laser scan (after [5.2])

that data can be preprocessed to enhance or extract features that are used in the integration. One common approach is model fitting, as illustrated for a laser scanner in Fig. 5.2. Once sensor information is available, it is often necessary to match the data with an existing model (Fig. 5.3). This model may be based on a priori known structure (e.g., a computer-aided design (CAD) model of the environment), or may have been built up from previously acquired data. Data as-

Fig. 5.3 An example environmental model for mobile robot localization (after [5.2])

Fig. 5.4 Estimation of position and orientation for the example mobile robot (after [5.2])

sociation methods are commonly employed to estimate the relationship between sensor data and the model of the environment. In our mobile robot localization example, the extracted line features are matched against a polygonal world model. This matching process can be performed in several different ways, but in general it is an optimization that maximizes the alignment of features to the model.

Once sensory data has been matched against the world model it is possible to update the model with new information contained in the sensor data. In the example, the orientation and position of the robot relative to the world model can be updated (Fig. 5.4) from the matched line segments.

Finally, it may be possible to develop a dynamical system model of the underlying state being estimated. Using such a system model, it is possible to predict how the world changes over time until new sensory data is acquired. This can be used within a feed-forward prediction process, which in turn simplifies data association for new sensory readings, as shown in Fig. 5.1.

With this as a prologue, we now turn to discuss each step of the perception process in greater detail.

5.3 Sensors

There are a variety of ways to classify sensors depending on what they measure, and how they measure it. As noted previously, proprioceptive sensors are used to measure the internal state of a robot, which might include position of different degrees of freedom, temperature, voltage on key components, motor current, force applied to an effector, and so forth. Exteroceptive sensors, on the other hand, generate information about the external environment in terms of distance to an object, interaction forces, tissue density, and so forth.

Sensors may also be differentiated based on whether they are passive or active. In general, an active sensor is one that emits energy into the environment, and measures properties of the environment based on the response. A passive sensor is one that is not active. Active sensors are generally more robust than passive sensors since they exert some control over the measured signal. For example, a passive stereo camera system must rely on the appearance of viewed surfaces when performing feature matching for triangulation (Chap. 31), whereas structured light systems project a pattern onto the scene and are thus less sensitive to scene characteristics. Even so, absorption, scattering or interference of the emitted signal can affect the performance of active sensors.

Proprioceptive sensors are typically passive and usually measure physical properties of the robot such as joint position, velocity, or acceleration, motor torque, and so forth. Exteroceptive sensors, on the other hand, can be further divided into contact and noncontact sensing. The contact sensors are typically the same modalities as used for proprioception, while noncontact sensor sensors involve most of the modalities that can be used for estimation of physical properties at a distance including intensity, range, direction, size, and so forth.

A classification of typical sensors according to method and typical application is shown in Table 5.1. More detail on methods of sensing, characterization of sensors, and general applications can for example be

found in the Handbook of Modern Sensors [5.3] and in Part C of this handbook.

Estimation of rotational motion is fundamental to control of robot manipulators and also for estimation of ego-motion for mobile systems. The most common sensor for measurement of rotation is the quadrature encoder. It is composed of a transparent disc, with two periodic patterns that are out of phase, as shown in Fig. 5.5. Through the use of counters it is possible

Table 5.1 Classification of sensors frequently used in robotics according to sensing objective (proprioception (PC)/exteroception (EC)) and method (active/passive)

Classification	Sensor type	Sens	A/P
Tactile sensors	Switches/bumpers	EC	P
	Optical barriers	EC	A
	Proximity	EC	P/A
Haptic sensors	Contact arrays	EC	P
	Force/torque	PC/EC	P
	Resistive	EC	P

	Ultrasound	EC	A
	Sound	EC	P

Fig. 5.5 Sketch of the quadrature encoder disc, and output from photodetectors placed over each of the two pattern. The corresponding state changes are shown on the right

to directly compute the motion and its direction (the phasing between sensors A and B in Fig. 5.5). In addition the disc is frequently fitted with a single dot on the outer rim for indexing (specification of a zero index). The density of the pattern determines the resolution of the measurements. When fitting the sensor to a motor before a reduction gear it is easy to achieve accuracies beyond $1/1000^\circ$.

For the estimation of force and torque at an end-effector it is possible to use piezoelectric elements. These elements generate a voltage that is proportional to the introduced deformation. Through careful placement it is possible to measure both force and torque. The sensors are used in robotic manipulation as part of assembly systems, deburring, etc. and also in medical applications for the estimation of stress and contact. Force/torque sensors are widely available in a range of sizes and dynamic ranges, including new flexible arrays that can be mounted on a variety of end-effectors (Fig. 5.6). These arrays are more commonly referred to as *tactile sensors* as they begin to simulate the human tactile sense. See Chap. 19 and [5.4, 5] for recent reviews of the state of the art in tactile sensing. Potential problems with force sensors are a dead band on initial contact, and noisy data from the basic sensing elements, which calls for signal processing to clean up the data.

Ego-motion estimation is an important part of almost all robotic systems. To this end it is possible to use inertial measurement units (IMU). An IMU typically includes both accelerometers and gyros. Accelerometers are sensitive to all types of acceleration, which implies that both translation motion and rotation (centripetal forces) are measured in combination. Joint IMU units allow the estimation of rotation and translation, and allow for double integration to estimation the velocity, orientation, and position of a system, as for example reported in [5.6]. One of the problems associated with the use of an IMU is the need for double integration. Small biases and noise can result in significant divergence in the final estimate, which calls for use of detailed models and careful calibration and identification of sensor characteristics. An example of data from a cross-bow DMU-6x unit for a car driving on an unpaved road is shown in Fig. 5.7.

Much early work on mobile robotics, underwater robots, and some medical robotics relies on ultrasonic ranging. The general class of sensors are often termed sound navigation and ranging (sonars). The general principle is that the system emits a sound pulse and awaits the return of echoes that have bounced off objects in the environment. Knowing the transmission speed in the medium and the time of flight it is possible to compute the distance. The method was widely used

Fig. 5.6 (a) TactArray, a flexible capacitive array tactile sensor from Pressure Profile Systems, Inc., is appropriate for sensing contact locations and areas under sliding conditions. (b) Conformable TactArray sensors can fit on a human or robotic hand (courtesy Pressure Profile Systems, Inc.)

Fig. 5.7 Example data from an IMU unit for driving on an unpaved road

in early robotics due to the availability of low-cost sensors with adequate performance. In underwater robotics this is still a primary sensor. Sonar is discussed in detail in Chap. 30.

Fig. 5.8 Example laser ranging sensor (SICK LMS291) that is widely used in mobile robotics

Recent progress on environmental modeling and navigation has, in many respects, been due to the emergence of low-cost high-fidelity laser scanning systems. The SICK series of laser scanners are time-of-flight scanners. The scanner sends out a pulse of light and measures the time to return. The standard scanner enables estimation of distances up to 80 m at centimeter or millimeter accuracy. The scanner measures distances in a plane with an angular resolution of $0.5\text{--}1^\circ$. The field of view is 180° resulting in 181–361 range measurements. The sensor data are contaminated by uniformly distributed noise, which must be considered in the detection of features or integration of data into a raw sensor map (Fig. 5.8).

Imaging sensors are a rich source of information for sensing and estimation. Imaging sensors come in a wide variety of configurations, varying according to imaging geometry, image resolution, sensor technology and the range of sensed spectral bands. Most readers are no doubt familiar with the traditional three-CCD, perspective color camera. In this case, there are three charge-coupled detector (CCD) arrays, each receiving a portion of the visible spectrum corresponding roughly to the human perception of red, green, and blue colors. A common and less expensive alternative is a so-called single-chip CCD camera. In this case, a special spatial array of color filters, usually referred to as a Bayer filter after its inventor Bryce Bayer, is employed. The resulting spatial array is subsequently processed (a process referred to as demosaicing) to provide color information for each pixel.

In the United States, image sensors traditionally contained 480 rows of 640 pixels according to the National Television System Committee (NTSC) standard created for analog transmission of television signals. The corresponding European standard, PAL, has 576 lines of 768 pixels. More recently, the advent of digital interfaces such as IEEE 1394 and

Fig. 5.9 The pinhole camera model

Fig. 5.10 Catadioptric image and the same image mapped to a cylindrical surface

USB 2.0 have allowed camera systems to be developed with significantly improved resolution ranging into the millions of pixels. At the same time, cost-effective infrared (IR) and ultraviolet (UV) cameras have become available, allowing the development of advanced multispectral image interpretation systems.

A traditional imaging sensor contains an optical system that focuses light on a planar imaging array. In most cases, this system can be modeled using the classical pinhole camera model (shown in Fig. 5.9). Given

a point $(x, y, z)^T$ in Euclidean space, the corresponding camera pixel coordinates $(u, v)^T$ are given by

$$\begin{aligned}(u - u_c) &= \frac{f}{s_x} \frac{x}{z}, \\(v - v_c) &= \frac{f}{s_y} \frac{y}{z},\end{aligned}\quad (5.1)$$

where f is the focal length of the lens system, u_c and v_c are the pixel coordinates of the center of projection, and s_x and s_y are the size of a single pixel on the imaging array. In practice, these models are also augmented with low-order models of image distortion. The values of these parameters for a given camera system can be determined experimentally using a variety of methods [5.7].

By combining a traditional perspective camera with a mirror, creating a so-called catadioptric system, it is possible to create imaging geometries that map fields of view as large as a hemisphere into a single image. Such systems are useful, for example, for surveillance, and their geometric properties provide for stable position referencing for mobile navigation [5.8]. An example image is shown in Fig. 5.10 together with the corresponding image when mapped to a cylindrical surface.

Active ranging cameras, which combine images from an optical camera with a dense range map, are now also widely available and quite cost effective. These systems perform triangulation between a light projector that throws a pattern with known structure into the scene, and a camera that views the scene and detects the pattern. By matching or correlating the pattern elements between the projector and the camera, and using the known relationship between them, it is possible to recover depth using standard methods. The camera/projector pair for depth recovery typically operate in the infrared to avoid the pattern being visible to the human eye. Thus, these systems typically include a third visible light camera to acquire a corresponding color image. Hence the name **RGB-D** (red–green–blue–depth) cameras. Fig. 5.11 shows two recent low-cost RGB-D products. In Fig. 5.12 is shown the fused output for a tabletop scene.

The discussion above has touched on the most commonly employed robotic sensing devices. Many special-purpose sensors are employed for specific applications. In medicine (Chap. 63), ultrasound, X-ray,

Fig. 5.11 Picture of proxim and kinect RGB-D sensors

Fig. 5.12 Example of fused range images from RGB-D camera and the same scene as an intensity textured mesh

computed tomography, and magnetic resonance imaging are commonly employed. Underground mapping makes use of ground-penetrating radar [5.9]. Underwater robotics makes use of many variations on acoustical sensors. Further discussions of these more task-specific sensing modalities can be found in the application chapters in Part C of this handbook.

5.4 Estimation Processes

As discussed in the introduction, there are many different techniques for combining information from sensors. The appropriate set of techniques depends, to a great degree, on what is known a priori about the environment, what information is necessary for the task at hand, and what models for the sensing system are appropriate. Common methodologies include simple voting-based methods, parametric and nonparametric statistical estimation techniques, fuzzy logic-based systems, and Dempster–Shafer theory.

To illustrate this point, consider the robot localization problem introduced in Sect. 5.2. At the outset, if nothing is known about the environment, the robot may acquire a laser scan and try to produce an initial model of the environment using line segments. Since nothing is known a priori, the system must estimate:

1. The number of line segments
2. The data association between line segments and observed data values
3. The parameters of the line segments themselves.

This is a challenging problem that can be attacked by simple voting techniques such as the Hough transform [5.10] or random sample consensus (RANSAC) [5.11] or more sophisticated unsupervised clustering methods such as *k*-means [5.12], expectation maximization (EM) [5.13], or generalized principal component analysis (GPCA) [5.14]. In many cases, this is a computationally intensive, iterative process.

Conversely, if a prior CAD model for the environment is known, then the problem is to produce a small set of parameters (translation and rotation) of the model to match the data. This problem can be solved, using feature matching by aligning observed points to the model with iterative closest-point algorithms (ICP) [5.15] or other efficient combinatorial matching algorithms such as Monte Carlo methods [5.16]. The best method to apply again depends to a great degree on the structure of the environment and what is known a priori.

Once an initial registration is known, new data can take advantage of the fact that strong prior knowledge is available. In particular, as the robot moves, the sensor data should change in a predictable fashion. Thus it is possible to make use of predictor–corrector methods such as the Kalman filter [5.17, 18] or sequential importance sampling [5.19], provided appropriate statistical characterizations of the sensing system are available. The data association problem, if present, can be addressed using a variety of general techniques such as EM [5.12] or more specialized mod-

ifications to the previously cited predictor–corrector methods [5.20].

It is often the case that sensor data is corrupted by occasional nonsensical values. For example, the laser range finder in our example may occasionally return a spurious range value due to a reflection. Many commonly used estimation techniques are not robust to such so-called data outliers. Techniques from robust statistics [5.21] can be used to improve the performance of sensing and estimation systems in such cases.

Finally, we may want to consider what information is actually important for the task at hand. Most of the techniques above presume that the goal is to produce an accurate estimate of a set of continuous parameters closely related to the underlying data. However, in some tasks, the parameter values themselves may not be what is of interest. For example, suppose that the goal of our robot is to drive through a doorway. Although this clearly depends on an ability to estimate the width of the door (a continuous parameter), the decision is ultimately binary. This problem can be codified as a *decision problem*. Decision problems can be modeled using concepts from *decision theory* [5.22] including zero–one loss functions, likelihood ratios, or probability ratios. For example, in the case of fitting through a door, for a low-priority task there may be a low cost associated with not attempting to move through this particular door (necessitating replanning to find an alternative route) relative to attempting to navigate through an opening that is too small (risking damage to the robot or the door, or both). Conversely, if the task is urgent, more risky behavior may be warranted.

For any given task (or decision), the amount of information necessary to reach the decision may vary, for example, if the doorway is quite wide, it may require relatively little information to safely navigate through it. Conversely, a tight fit may require close inspection before a decision can be reached. The problem of determining the type and/or amount of information necessary to reach a decision is referred to variously as the *sequential sampling problem* [5.22], the sensor control problem, or the sensor planning problem [5.23–25].

5.4.1 Point Estimation

In our robot localization example we saw several cases where the key problem was to estimate an unknown quantity that can be represented as a point in a vector space. Examples include the location of a two-dimensional (2-D) or three-dimensional (3-D) point or the location of a robot. We also saw examples where the problem was to locate the pose (position and orien-

tation) of the robot, or parameters of a line segment. The latter differ in that the underlying parameter space is not a vector space. This introduces some additional unique problems. We refer the reader to [5.26, 27] for further discussion, and in the remainder of this chapter restrict our attention to *point estimation* problems on vector spaces. In our discussion, we assume the reader is familiar with multivariate Gaussian distributions as described in [5.28] and basic linear algebra [5.29].

In the remainder of this section, we consider the following general problem.

Given: an observation model

$$y = f(x, \eta) . \quad (5.2)$$

Estimate: $x \in \text{Re}(n)$ from observations $y \in \text{Re}(m)$ where η is an unknown disturbance taking values in $\text{Re}(k)$ and f is a known mapping from $\text{Re}(k+n)$ to $\text{Re}(m)$.

We divide our discussion into two topical areas:

- Methods for performing estimation on batch and sequential data when f is linear,
- Methods for performing estimation on sequential data when f is nonlinear.

Estimation Techniques for Batch and Sequential Data with Linear Models

In this section, we discuss linear and linearized estimation techniques for sequential data, including the Kalman filter and extensions thereof. Our goal is to provide an overview of techniques available. The reader may also wish to consult more in-depth references such as [5.18, 30, 31] and (Chap. 35) for additional information.

We first consider the case when f in (5.2) is linear in its arguments. In this case, we can write

$$y = \mathbf{F}x + \mathbf{B}\eta , \quad (5.3)$$

where $\mathbf{F} \in \text{Re}(m \times n)$ defines the (linear) relationship between the unknown x and the observation y and $\mathbf{B} \in \text{Re}(m \times m)$. For the moment, we will drop \mathbf{B} and assume that η represents the complete disturbance model of the system.

The *least-squares* method of estimating x from y proceeds by solving the optimization problem

$$\min_x \|\mathbf{F}x - y\|^2 . \quad (5.4)$$

This optimization has a unique solution \hat{x} if and only if the matrix \mathbf{F} has full column rank. In this case, the solution can be computed by solving the following linear

system

$$\mathbf{F}^T \mathbf{F} \hat{x} = \mathbf{F}^T y . \quad (5.5)$$

In some cases, there may be reason to believe that some observed elements are more reliable than others, and hence should contribute more to the final estimate. This information can be incorporated by modifying (5.4) to include a diagonal positive-definite weighting matrix \mathbf{W} as

$$\min_x (\mathbf{F}x - y)^T \mathbf{W} (\mathbf{F}x - y) . \quad (5.6)$$

The solution is then given by solving

$$(\mathbf{F}^T \mathbf{W} \mathbf{F}) \hat{x} = \mathbf{F}^T \mathbf{W} y . \quad (5.7)$$

Although (5.3) included a disturbance component (in the form of η), the parameter estimates computed in (5.5) or (5.7) made no explicit use of this quantity. However, we can often model the noise characteristics of the underlying sensor using a statistical model and recast our original estimation problem to incorporate this information. One common method is to compute the *maximum-likelihood estimate* (MLE), which is a value \hat{x} such that

$$p(y|\hat{x}) = \max_x p(y|x) . \quad (5.8)$$

For the linear additive model of (5.3), the likelihood function can be expressed in a particularly simple form. Suppose that η is described by a fixed, known probability density function D . The likelihood function is then given by

$$p(y|x) = D(y - \mathbf{F}x) . \quad (5.9)$$

The MLE can be related to the previous least-squares method as follows. Suppose that $\eta \sim N(0, \mathbf{\Lambda})$, where N denotes a multivariate Gaussian density function with (mean) 0 and covariance $\mathbf{\Lambda}$. Upon observing that the maximizing the value of the likelihood function is equivalent to minimizing the negative log of the likelihood function, a short series of calculations shows that the optimal maximum-likelihood estimate is computed by weighted least squares with $\mathbf{W} = \mathbf{\Lambda}^{-1}$.

Finally, there is often a reason to include the idea that some parameters are more likely a priori to occur as others. For example, when observing a car driving on an expressway, a velocity of 60 mph is much more likely than either 20 or 300 mph. This information can be captured in *prior statistics* on the unknown value x .

Given a prior probability density on x , $p(x)$, Bayes theorem states that

$$p(x|y) = \frac{p(y|x)p(x)}{p(y)} = \frac{p(y|x)p(x)}{\int p(y|x)p(x) dx}. \quad (5.10)$$

The *maximum a posteriori probability* (MAP) estimate is the value \hat{x} such that

$$p(\hat{x}|y) = \max_x p(x|y). \quad (5.11)$$

In general, the solution to this optimization problem can be quite complex. Rather than pursue this course further, we consider another alternative. Namely, provided the second moments of $p(x|y)$ exist, it is possible to produce a *least-squares* estimate, in a statistical sense, by solving the following optimization problem over an unknown function δ

$$\min_{\delta} E \|\delta(y) - x\|^2. \quad (5.12)$$

That is, the best function δ is one that produces an estimate of x from y with *minimum mean-square error* (MMSE). Thus, the estimator δ is often referred to as an MMSE estimator.

It can be shown that, in the general case, the *optimal* decision rule δ^* is the conditional mean [5.22]

$$\delta^*(y) = E[x|y]. \quad (5.13)$$

Unfortunately, this expression, as with the MAP estimate defined above, can be extremely difficult to compute for the general case. Later we consider methods for computing approximations to (5.13). For now, we again consider our previous linear observation model (5.3) (without B). Additionally, we suppose that x and η are *independent* random variables with finite second moments, and both are *zero-mean* random variables. Note that the latter is not really a restriction since it can be accomplished by simply defining a new variable $x' = x - E[x]$. Finally, we will consider only *linear* functions δ , that is, we can write $\hat{x} = \delta(y) = \mathbf{K}y$.

With this, (5.12) can be expanded as

$$\begin{aligned} E \|\delta(y) - x\|^2 &= E \|\mathbf{K}y - x\|^2 \\ &= E \|\mathbf{K}(\mathbf{F}x + \eta) - x\|^2 \\ &= E \|(\mathbf{K}\mathbf{F} - \mathbf{I})x + \mathbf{K}\eta\|^2 \\ &= \text{tr}[(\mathbf{K}\mathbf{F} - \mathbf{I})\mathbf{\Lambda}(\mathbf{K}\mathbf{F} - \mathbf{I})^T + \mathbf{K}\mathbf{\Sigma}\mathbf{K}^T]. \end{aligned} \quad (5.14)$$

Here, the independence of x and η and the fact that they are both zero mean has eliminated several terms. The final step makes use of the fact that $\|x\|^2 = \text{tr}(xx^T)$.

Taking derivatives with respect to \mathbf{K} and setting them equal to zero yields the solution

$$\mathbf{K} = \mathbf{\Lambda}\mathbf{F}^T(\mathbf{F}\mathbf{\Lambda}\mathbf{F}^T + \mathbf{\Sigma})^{-1}. \quad (5.15)$$

Thus, in this case the optimal estimate is given by a linear function of the observation, where the linear term depends only on the variance of the underlying random variables and the linear term defining the observation system.

If x is not zero-mean, but has mean μ , it is not hard to show that the optimal estimate is

$$\hat{x} = \mathbf{K}y + (\mathbf{I} - \mathbf{K}\mathbf{F})\mu, \quad (5.16)$$

and that the variance of the estimate $\mathbf{\Lambda}^+$ is

$$\mathbf{\Lambda}^+ = (\mathbf{I} - \mathbf{K}\mathbf{F})\mathbf{\Lambda}. \quad (5.17)$$

The interested reader may wish to work this out for a few simple cases, for example, if $\mathbf{\Lambda} = \mathbf{\Sigma}$ and $\mathbf{F} = \mathbf{I}$, $\mathbf{K} = 1/2\mathbf{I}$ and thus $\hat{x} = y + \mu$ – a simple average – with variance $\mathbf{\Lambda}^+ = 1/2\mathbf{\Lambda}$.

When both the observation noise and prior statistics are Gaussian distributions, then it can be shown that the solution we have derived is also the MAP estimate for the unknown x [5.22].

The Kalman Filter

With this as background, we are now in a position to define the discrete-time Kalman–Bucy filter [5.32] for linear systems. Consider the following time-series model

$$x_{t+1} = \mathbf{G}x_t + w_t, \quad (5.18)$$

$$y_t = \mathbf{F}x_t + \eta_t, \quad (5.19)$$

where \mathbf{G} is an $n \times n$ matrix describing the system time evolution and x_0 is distributed according to a Gaussian distribution with mean \hat{x}_0 and variance $\mathbf{\Lambda}_0$. In addition w_t and η_t are zero-mean Gaussian independent random variables for all t , w_t is independent of $w_{t'}$ for all $t \neq t'$, and likewise η_t is independent of $\eta_{t'}$ for all $t \neq t'$. Finally, η_t has variance $\mathbf{\Sigma}_t$ and w_t has variance $\mathbf{\Omega}_t$.

Given an observation y_1 it is possible, using the derivation of the previous section, to compute an updated estimate \hat{x}_1 with variance $\mathbf{\Lambda}_1$. Note, that the solution is a linear combination of two Gaussian random variables: the observation value y_1 and the prior estimate \hat{x}_0 . As any linear combination of Gaussian random variables is also a Gaussian random variable, it follows that the updated estimate is also Gaussian.

Fig. 5.13 A summary of the Kalman filter

Now, we add one additional step: projection through the dynamics model. To describe this, superscripts minus and plus will denote before and after the estimation step, respectively. Thus, given an estimate \hat{x}_t^+ with variance Λ_t^+ , the projection ahead one time step produces

$$\hat{x}_{t+1}^- = G\hat{x}_t^+, \quad (5.20)$$

$$\Lambda_{t+1}^- = G\Lambda_t^+G^T + \Omega_t. \quad (5.21)$$

At this point, a new observation y_{t+1} is acquired and the cycle repeats. The summarization of the complete Kalman filtering algorithm for linear systems is shown in Fig. 5.13.

It is possible to show that the Kalman filter is the *optimal* filter, under the stated assumptions, in the mean-square sense. It is also the optimal *linear* filter when either or both Gaussian assumptions do not hold.

Nonlinear Estimation Techniques for Sequential Data

The results of the previous subsection presume a linear form for the relationship between the observation and system state, additive noise, and a linear relationship describing the state evolution. Furthermore, the stated results are globally optimal for systems with Gaussian observation and driving noise, but are only the best *linear* estimator if the noise sources are non-Gaussian.

As noted at the outset, the more general nonlinear (discrete-time) system description is

$$\begin{aligned} x_{t+1} &= g_t(x_t) + w_t, \\ y_t &= f_t(x_t) + \eta_t, \end{aligned} \quad (5.22)$$

where, for the moment, the noise model continues to be additive.

Although this model contains nonlinear elements, it is still possible to apply a variant of the Kalman filter,

the extended Kalman filter (EKF) by making use of the Taylor-series expansion of the nonlinear elements about the current estimates. Let \mathbf{J}_f (resp. \mathbf{J}_g) denote the Jacobian matrix of the function f (resp. g). Supposing that an estimate at time step $t-1$ exists, the first-order expansion of (5.22) about this point yields

$$x_{t+1} = g_t(\hat{x}_{t-1}) + \mathbf{J}_g(\hat{x}_{t-1})(x_t - \hat{x}_{t-1}) + w_t, \quad (5.23)$$

$$y_t = f_t(\hat{x}_{t-1}) + \mathbf{J}_f(\hat{x}_{t-1})(x_t - \hat{x}_{t-1}) + \eta_t. \quad (5.24)$$

Rearranging yields a linear form appropriate for the previously defined Kalman filter

$$\tilde{x}_{t+1} = x_{t+1} - g_t(\hat{x}_{t-1}) + \mathbf{J}_g\hat{x}_{t-1} = \mathbf{J}_{g_t}x_t + w_t, \quad (5.25)$$

$$\tilde{y}_t = y_t - f_t(\hat{x}_{t-1}) + \mathbf{J}_f\hat{x}_{t-1} = \mathbf{J}_{f_t}x_t + \eta_t. \quad (5.26)$$

In this form, \tilde{x} and \tilde{y} are new *synthetic* state and observation variables, $\mathbf{J}_g(\hat{x}_{t-1})$ plays the role of G , and $\mathbf{J}_f(\hat{x}_{t-1})$ plays the role of F .

It is worth noting that the EKF iterations are essentially a form of weighted Newton iterations (i. e., an iterative nonlinear estimation method). As a result, it is often useful to iterate more than once *on the same observation* while holding the variance terms fixed. This allows the estimator to converge to a solution in the presence of large disturbances or significant nonlinearities. Only after convergence are the variance terms updated. This version of the Kalman filter is referred to as the *iterated extended Kalman filter* (IEKF).

5.4.2 Other Approaches to Estimation

In the previous section, we reviewed a common and widely used estimation method. However, there are several alternative methodologies for solving parameter estimation problems. Here we briefly introduce two: sequential importance sampling and graphical models.

Sequential Importance Sampling

Much of the discussion heretofore has centered around the notion of approximating everything known about the system state using an estimated mean and covariance. An alternative presents itself by simply going back to Bayes theorem which states, in general, that

$$p(x_n|y_1, y_2 \dots y_n) = \frac{p(y_1, y_2 \dots y_n|x_n)p(x_n)}{p(y_1, y_2 \dots y_n)}. \quad (5.27)$$

Assuming that y_n is independent of all prior observations and states given x_n , and that x_n is independent of x_{n-k} for $k > 1$ given x_{n-1} , this expression simplifies

to

$$p(x_n | x_{n-1}, y_n) = \frac{p(y_n | x_n) p(x_n | x_{n-1})}{p(y_n | x_{n-1})}. \quad (5.28)$$

Recall that the optimal mean-square estimate is given by the conditional mean which, in this case, is

$$\delta^*(y_n) = E[x_n | y_n]. \quad (5.29)$$

In fact, we essentially showed that the Kalman filter is a special case of this result for linear systems corrupted by Gaussian noise.

The difficulty in implementing this procedure in the general case ultimately comes down to the problem of representing and computing with the distributions that arise in the nonlinear, non-Gaussian case. However, suppose that the heretofore continuous variable x_n only took on a discrete set of values. In this case, computing Bayes theorem and other associated statistical quantities reduces to a straightforward set of computations on this discrete set of variables. This can be simply done for any distribution and any set of transformations.

Sequential important sampling (also known as particle filtering, condensation, and a variety of other names) is a way of applying this approach to continuous variables in a statistically sound manner. In order to perform sequential importance sampling, it is assumed that:

1. It is possible to *sample from* the likelihood function $P(y_n | x_n)$, and
2. It is possible to *sample from* the dynamical model $P(x_n | x_{n-1})$.

Note the emphasis on sampling – there is no need to explicitly exhibit an analytical form of the likelihood function or of the dynamical model.

Given this, sequential important sampling, in its simplest form, can be written as follows:

1. Let $\pi_{n-1} = \{ \langle x_{n-1}^k, w_{n-1}^k \rangle, k = 1, 2, \dots, N \}$ represent a set of sample points x_{n-1}^k together with a set of weights w_{n-1}^k with $\sum w_{n-1}^k = 1$.
2. Compute a new set of N samples $\pi_n = \{ \langle x_n^k, 1/N \rangle, k = 1, 2, \dots, N \}$ as:
 - a) Choose a sample point x_{n-1}^{k-1} with probability proportional to its weight w_{n-1}^{k-1} ;
 - b) Sample from $P(x_n | x_{n-1}^k)$ given x_{n-1}^k with weight $1/N$;
3. Compute $\pi_n = \{ \langle x_n^k, P(y_n | x_n^k) \rangle, k = 1, 2, \dots, N \}$.

It is easy to see that this set of steps is now in the form of a recursive filter. Furthermore, at any time any statistic of the associated distribution can be approximated from the set of samples and associated weights.

Sampling-based filters of this form have found wide applicability in a variety of challenging areas where linear estimation techniques do not suffice. These techniques have been particularly successful, for problems with low state dimension (typically $n \leq 3$) and well-constrained dynamics. For higher-dimensional problems or systems exhibiting high dynamic variability, the number of particles necessary to obtain good approximations can become prohibitively large. However, even in these cases, sampling-based systems can sometimes be engineered to produce acceptably good results.

Graphical Models

Graphical models are a class of models that represent dependence and independence relationships among a set of variables. Common examples of graphical models include Bayes nets, influence diagrams, and neural nets. Graphical models are quite general – indeed much of this chapter could have been written by first defining graphical models, and exploring specializations that lead to the Kalman Filter, for example. Here, for reasons of space, we focus on Bayes nets as a specific example of graphical models.

A Bayesian network is a directed acyclic graph consisting of nodes representing random variables, and directed arcs representing probabilistic relationships between pairs of random variables. Let $\text{parents}(X)$ denote the set of nodes which have arcs terminating at X , and let X_1, X_2, \dots, X_N be the N random variables in the graph. Then we can write

$$P(X_1, X_2, \dots, X_N) = \prod_{i=1}^N P(X_i | \text{parents}(X_i)). \quad (5.30)$$

For example, a Bayesian network representing a mobile robot performing localization is shown in Fig. 5.14. This graphical model encodes the sequential form of the problem and is thus an example of a so-called *recurrent*

Fig. 5.14 An example of robot localization expressed as a graphical model

network. More discussion of such models can be found in [5.33].

The structure of a Bayesian network encodes various independence relationships among variables. By exploiting these independence relationships, it is possible to design efficient inference algorithms. In particular, graphs which are acyclic even in their undirected form (referred to as *polytrees*) admit linear time inference algorithms. More general graphs can be solved using various types of iterative methods. In particular, if the distributions in the network are of a continuous type, variations on sequential importance sampling can be used to solve problems in an approximate sense [5.34].

Conditional Random Fields

In many cases of interest, including many of the examples in this chapter, the end goal is to infer or predict a value or label from observed data. We might then frame the problem by exploring the joint distribution $P(X, Y)$ where X represents some data that is *observed* and Y is what we would like to infer. Recall that

$$P(X, Y) = P(Y|X)P(X).$$

If we take $X = x$ for some observed values x , then we see that $P(X)$ becomes constant, and inferring a value for Y depends only on $P(Y|X)$. If we were to apply a Bayes Net to this problem, the model would represent the complete joint probability distribution on X and Y , what is referred to as a *generative model*. But, if we know X is always observed, then much of this structure is irrelevant to our problem – we don't care about the probabilistic structure of X . This observation has given rise to a specialization of graphical models referred to as *Conditional Random Fields*, or *CRFs* for short.

The immediate value of *CRFs* is their economy and expressivity compared to graphical models. This has immediate positive implications for the complexity of both learning and inference. Traditionally *CRF* models are learned using maximum likelihood-based methods using gradient descent or other unconstrained optimization techniques. However, recent methods like Cutting Planes [5.35] and Block Coordinate Frank Wolfe [5.36] pose it as a constrained optimization problem in the form of a Structural Support Vector Machine. These techniques tend to be more computationally efficient and are often more accurate.

CRFs have proven to be very general, and are now extremely widely used for image processing, natural language processing, video processing – nearly any problem where there is a series of data elements

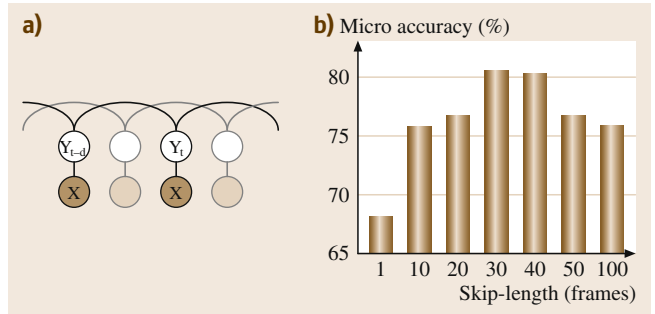

Fig. 5.15 (a) A skip chain *CRF* for inferring symbolic labels (Y) from robot kinematic and video data (X) acquired while a user performed a surgical training task. (b) The change in classification accuracy as a function of the skip length (images courtesy of Colin Lea)

from which some prediction is to be performed. For example, Fig. 5.15 shows the graphical structure of a skip-chain *CRF* designed to compute gesture labels from kinematic and video data acquired from a surgical robot [5.37]. This can be viewed as a discriminative generalization of a Hidden Markov Model (a generative model) that is designed to capture dependencies over a specified period of time (the *skip*). The right side shows the change in labeling performance as a function of the skip length which is now a *tunable* parameter of the model.

An in-depth discussion of *CRFs* goes well beyond this chapter. The interested reader is referred to [5.38, 39] to learn more about the underlying theory and application of *CRFs*. Because of their high interest, there are a number of open-source packages for developing and applying *CRFs* including PyStruct [5.40] for Python and *CRF++* for C++.

5.4.3 Robust Estimation Methods

In our previous discussions, we generally assumed that all of the data was *good*, meaning that it was perhaps corrupted by noise but ultimately carried information about the problem at hand. However, in many cases, the data may contain so-called *outliers* – data points that are either much more highly corrupted than typical data, or which are completely spurious. For example, in our mapping application we might occasionally obtain range data through multiple reflections. Thus, while scanning a straight wall, most of the points would lie on a straight line, but occasionally we would have a data point that has a completely inconsistent range value.

Many common estimation methods are quite sensitive to data outliers. Consider a very simple case: estimating a single scalar value x by averaging a series of observations X_1, X_2, \dots, X_N . Then we can write our

estimate \hat{x} as

$$\hat{x} = \sum_{i=1}^N X_i / N. \quad (5.31)$$

Now, without loss of generality, suppose that X_N is an outlier. We can rewrite the above as

$$\hat{x} = \sum_{i=1}^{N-1} X_i / n + X_N / n. \quad (5.32)$$

It is now easy to see that we can produce *any* value of \hat{x} by manipulating X_N . In short, a single outlier can create an arbitrarily poor estimate. More generally, the solution to any least-squares problem, e.g., estimating a line from laser range data, takes the general form $\hat{x} = \mathbf{M}y$. By the same argument as above, it is easy to show that any least-squares solution is likewise susceptible to outliers.

The field of *robust statistics* studies the problem of estimation or decision making when the underlying data are contaminated by outliers. In robust statistics, there are two important concepts: the *breakdown point* and *influence function*. The breakdown point is the proportion of outliers (i.e., data with arbitrarily large errors) that an estimator can tolerate before producing arbitrarily large errors in an estimate. We argued above that least-squares methods have a breakdown point of 0% since the estimate can be perturbed arbitrarily far by a single observation. By comparison, we might compute an estimate by taking the median of the data, which has a breakdown point of 50% – up to half of the data can be outliers and meaningful results may still be produced.

Whereas the breakdown point quantifies *how many* outliers can be tolerated, the influence function quantifies *how much* an outlier affects an estimate. In the case of least squares, the influence function is linear. One way of creating new estimators with better robustness is the method of *M-estimators* [5.21]. To produce an M-estimate, we consider the following minimization problem

$$\min_{\hat{x}} \sum_{i=1}^N \rho(\hat{x}, y_i). \quad (5.33)$$

Note that defining $\rho(a, b) = (a - b)^2$ leads to a least-squares solution. However, we can now choose other functions with better resistance to outliers. Fig. 5.16 shows three common examples.

Note that, in general, the optimization of (5.33) is nonlinear and the result will often not exist in closed form. Interestingly, it is often possible to

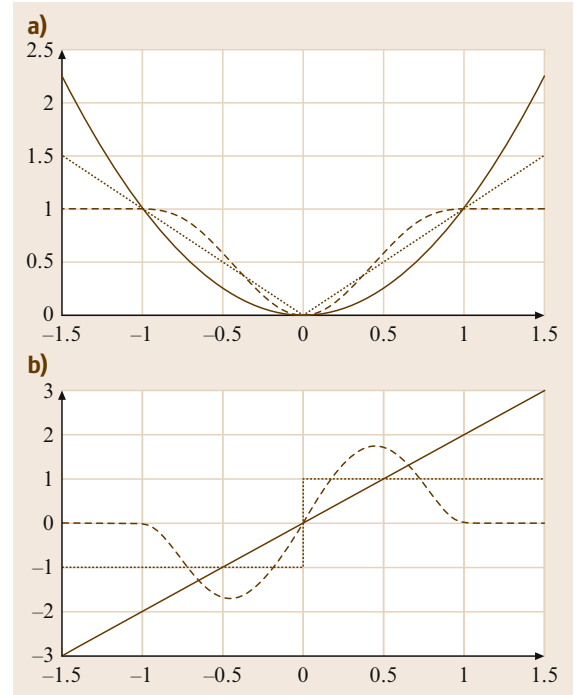

Fig. 5.16 (a) Three common robust M-estimation functions: the square function, the absolute value, and the Tukey biweight function. (b) The corresponding influence functions

solve this problem using the method of *iteratively reweighted least squares (IRLS)* [5.30, 41]. The idea behind IRLS is quite simple. Recall that in (5.7) we introduced a weighting matrix \mathbf{W} . Suppose that, through some means, we knew which data points were outliers. In this case, we could simply set the weights for those points to zero, and the result would be the least-squares estimate on the remaining (good) data.

In IRLS, we alternate between hypothesizing outliers (through reweighting) and solving to produce a solution (through least squares). Typically, the weight for a point depends on the residual error of the estimate. That is, suppose we compute

$$r = y - \mathbf{F}\hat{x}. \quad (5.34)$$

Let $\psi(y) = d\rho/dx|_{\hat{x}}$; then we can set $\mathbf{W}_{i,i} = \psi(y)/r_i$. It can be shown that in many cases this form of weighting will lead to convergence. An example of using IRLS techniques for video tracking is shown in Fig. 5.17.

Voting-Based Methods

Another common method for dealing with outliers is to choose a set of data and let it *vote* for a result. We dis-

Fig. 5.17a–c An example of using an M-estimate implemented via [IRLS](#) for visual tracking (after [5.42]). (a) Results of a face tracker in a single frame of video. The black frame corresponds to a tracking algorithm without outlier rejection and the white frame corresponds to the algorithm with outlier rejection. (b) Magnified view of the region in the white frame; (c) the corresponding weighting matrix in which darker areas mark outliers

cuss two common methods: [RANSAC](#) [5.11] and least median of squares ([LMedS](#)) [5.43].

In both cases, we start with the idea that, amidst all of the data (including outliers), there is an estimate that is consistent with the *good* data. The problem is to choose that estimate. Consider, however, our problem of estimating a line from laser data, and suppose we have 100 laser points. All we really need is to choose two points correctly, fit a line, and then count how many other points are consistent with this line. If we (conservatively) estimate that 3/4 of the data is good, then the odds of choosing two *good* points is 9/16, or equivalently, the odds of one or both points being outliers is 7/16. If we now repeat this process a few (e.g., ten) times, then the odds that *all* of our choices are bad is $(7/16)^{10} = 0.025\%$. To put it in other terms, there is a 99.975% chance we have chosen a *good* pair of points.

How do we decide to accept a sample? In [RANSAC](#), we *vote* by counting the number of samples that are consistent with an estimate to within a given distance threshold. For example, we would choose points that are within a fixed distance to the line we estimated. We choose the candidate estimate with the largest number of votes. In [LMedS](#), we instead compute the median distance of all of the samples to the line. We then choose the estimate with the least median value.

It is not hard to see that [LMedS](#) has a breakdown point of 50% of the data. [RANSAC](#), on the other hand, can have a breakdown point that is potentially larger, but it requires the choice of a threshold. [RANSAC](#) also has the advantage that, once the inliers are identified, it is possible to compute a least-squares estimate from them, thus reducing the noise in the estimate.

Both [RANSAC](#) and [LMedS](#) can also provide good starting solutions for a robust iterative method such as [IRLS](#).

5.4.4 Data Association Techniques

The previous section considered the case where there is a *known* relationship between observations and a quantity to be estimated. However, as was illustrated in our initial mobile robot mapping problem, it may be the case that we also have to compute this correspondence in conjunction with estimation. In this case, an essential step in estimation is the *data association* problem: producing a correspondence between the observed data and quantities to be estimated.

The literature on this problem is enormous; here we will focus on a few specific methods that have found wide use. We will also separate our discussion into *causal* (or sequential) association methods commonly used when filtering time-series data and *noncausal* (or batch) methods that can be used when the complete data set is available for processing. The latter is typically treated with methods for data *clustering*.

In both cases, we can extend our previous models and notation to include uncertainty as to the underlying source of the data. To this end, we will use a superscript on quantities to denote the observation model. Thus, our observation model becomes

$$x_{t+1}^k = g^k(x_t^k) + w_t^k, \quad (5.35)$$

$$y_t^k = f_t^k(x_t^k) + \eta_t^k, \quad (5.36)$$

where $k = 1 \dots M$.

Clustering on Batch Data

Following the same course as our previous discussion on point estimation, let us first consider the case where we do not make any statistical assumptions about the data, and we have no system dynamics. Thus, we are simply given the observations y_1, y_2, \dots, y_M . We have unknown underlying parameters x^1, x^2, \dots, x^N (for the moment, we take N as known). Our goal is to compute an *association mapping* π such that $\pi(j) = k$ if and only if y_j arose from the model parameters x^k .

k -Means Clustering

The k -means algorithm for clustering and data association is simple, well established, and forms a good starting point for our discussion. Here, we assume that $f(x) = x$ – that is, we are provided with noisy observations of the underlying state vectors. The k -means algorithm then proceeds as follows:

1. Pick N cluster centers $\{\hat{x}^i\}$.
2. For each observation y_j , associate it with the closest cluster center, that is, set $\pi(j) = i$, where

$$d(\hat{x}^i, y_j) = \min_k d(\hat{x}^k, y_j) \quad (5.37)$$

for some distance function d (typically the Euclidean distance).

3. Estimate the mean of the observation associated with each cluster center as

$$\hat{x}^i = \sum_{j, \pi(j)=i} y_j. \quad (5.38)$$

4. Repeat steps 2 and 3.

In many cases and with good initialization, k -means works quite well. However, it can also fail to produce good clusters, and there is no guarantee that it will even converge to a solution. It is common to repeat the algorithm several times from different initial conditions and take the result that has the *best* outcome. Note also that the extension to linear observation models is straightforward by including \mathbf{F} in (5.3) by defining

$$d(\hat{x}^i, y_j) = \|\mathbf{F}\hat{x}^i - y_j\| \quad (5.39)$$

and replacing (5.38) with the corresponding least-squares estimator. Going a step further, if we have a statistical model for observed data, then we could make use of the likelihood function introduced earlier and define $d(\hat{x}^i, y_j) = p(y_j|\hat{x}^i)$ and make use of the MLE in (5.38).

One disadvantage of the k -means algorithm is that, even when we have known statistical models, it is not guaranteed to converge. However, a variation, known as *expectation maximization*, can be shown to converge.

Expectation Maximization for Data Association and Modeling

The expectation-maximization (EM) algorithm [5.44] is a general statistical technique for dealing with missing data. In previous discussion, we made use of maximum-likelihood estimation to maximize the conditional probability of observed data given a set of unknown parameters. However, our use of MLE presumed that we had complete knowledge of the data. In particular, we knew the association between the data elements and models.

Let us now assume that some of our data is missing. To this end, define \mathcal{Y}_O and \mathcal{Y}_U as the *observed* and *unobserved* data, respectively. We then note that we can write

$$p(\mathcal{Y}_O, \mathcal{Y}_U|x) = p(\mathcal{Y}_U|\mathcal{Y}_O, x)p(\mathcal{Y}_O|x). \quad (5.40)$$

Suppose now that we make a guess for \hat{x} , and we have a distribution over the unknown data \mathcal{Y}_U (where this comes from we will discuss in a minute). It follows that we could compute the *expected value* of the log-

likelihood function (recall that maximizing the log likelihood is equivalent to maximizing the likelihood) as

$$\mathcal{Q}(x, \hat{x}) = E_{\mathcal{Y}_U} [\log p(\mathcal{Y}_O, \mathcal{Y}_U|x) | \mathcal{Y}_O, \hat{x}]. \quad (5.41)$$

Note that we differentiate between the fixed value \hat{x} that is usually needed to define the distribution over the unknown data and the unknown x of the log-likelihood function.

Ideally, we would then like to choose values for x that make \mathcal{Q} large. Thus, we can choose a new value according to the iterative rule

$$\hat{x}_i = \arg \max_x \mathcal{Q}(x, \hat{x}_{i-1}). \quad (5.42)$$

What can be shown is that this iteration will converge to some local maximum of the objective function \mathcal{Q} . It is important to note that there is no guarantee that this is, however, the *global* maximum.

How do we connect this with clustering? We consider the observed data to be just that, the data we have observed. Let the unobserved data be the *association values* $\pi(j)$, $j = 1, 2, \dots, M$ that determine which model the observed data items originate from. Note that this is a discrete random variable. Let us further assume that N underlying clusters are distributed according to a Gaussian distribution with mean x_i and covariance Λ_i . Let the unconditional probability that a particular data item y_j comes from cluster i be α_i . The unknown parameters are then $\theta = \{x_1, x_2, \dots, x_N, \Lambda_1, \Lambda_2, \dots, \Lambda_N, \alpha_1, \alpha_2, \dots, \alpha_N\}$. We now use $-$ and $+$ to denote prior and updated parameter estimates, respectively. For conciseness, we also define $w_{i,j} = p(\pi_j = i | y_j, \theta)$ and we use a superscript $+$ to denote updated parameter estimates. Then, after a series of calculations [5.44], the EM algorithm for data clustering becomes

E-Step:

$$w_{i,j} = \frac{p(y_j | \pi(j) = i, \theta) \alpha_i}{\sum_i p(y_j | \pi(j) = i, \theta) \alpha_i}. \quad (5.43)$$

M-Step:

$$\hat{x}_i^+ = \frac{\sum_j y_j w_{i,j}}{\sum_j w_{i,j}}, \quad (5.44)$$

$$\Lambda_i^+ = \frac{\sum_j y_j (y_j)^t w_{i,j}}{\sum_j w_{i,j}}, \quad (5.45)$$

$$\alpha_i^+ = \frac{\sum_j w_{i,j}}{\sum_i \sum_j w_{i,j}}. \quad (5.46)$$

From this, we can see that EM produces a type of soft clustering, as opposed to k -means which produces

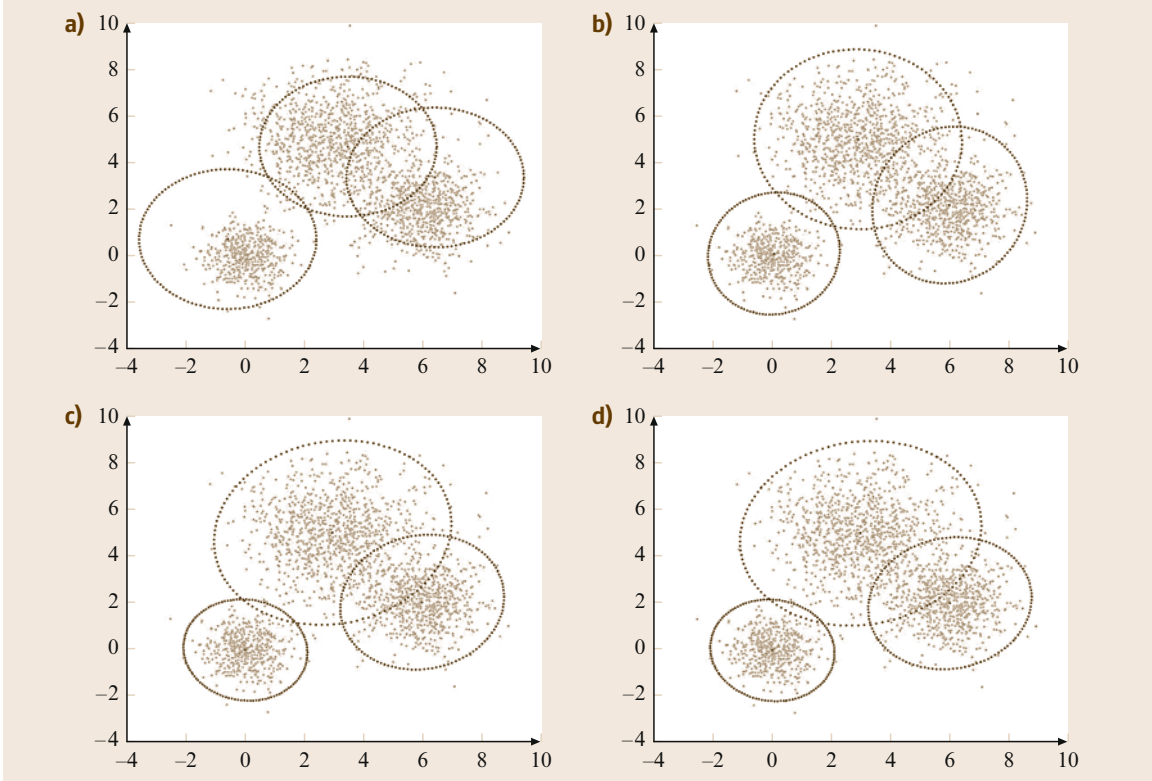

Fig. 5.18a–d An example of clustering using expectation maximization. The figures are the results at iterations (a) 1, (b) 2, (c) 5, and (d) 10

specific decisions (in terms of $w_{i,j}$) as to which cluster an observation belongs. In fact, the result of estimation is the maximum-likelihood estimate of a *Gaussian mixture model* which has the form

$$p(y|\theta) = \sum_j \alpha_j N(y|\hat{x}_j, \Lambda_j), \quad (5.47)$$

where $N(\cdot)$ denotes a Gaussian density function. Fig. 5.18 shows the results of executing the EM algorithm on data sampled from a Gaussian mixture model.

Recursive Filtering

In the batch methods described above, we do not have a priori information on state parameters. In the case of recursive filtering, we have the advantage that prior state estimates, \hat{x}_t^k and Λ_t^k , are available for processing at time $t+1$. As before, for data $y_i^j, i=1 \dots N$, the problem is to determine a mapping $\pi: \{1 \dots N\} \rightarrow \{1 \dots M\}$ which *associates* data element i to model $k = \pi(i)$. In some cases, it is also useful to include an *outlier process* to handle data that comes from no known model. For this purpose, we can include 0 in the range of the function, and use the mapping to zero as an outlier.

Nearest-Neighbor Association

Analogous to k -mean clustering, a simple way of producing a data association is to compute the data association value as

$$\pi(i) = \arg \min_j d(\mathbf{F}^j \hat{x}^j, \hat{y}^i). \quad (5.48)$$

However, nearest-neighbor methods do not take into account what we know about either the sensor data or the estimate. That is, we may have a very very good estimate of some model i and a very very bad estimate for some other model j . If a sensor observation is equidistant between them, does it make sense to flip a coin? Odds are that it is more likely to come from j (with a larger variance) than i (with a smaller variance).

A commonly used measure that can take this into account is the *Mahalanobis distance* [5.45]. The idea is to weight each value by its variance as

$$m(y_1, y_2) = (y_1 - y_2)(\Lambda_1 + \Lambda_2)^{-1}(y_1 - y_2)^T. \quad (5.49)$$

Thus, distances are scaled inversely with uncertainty. In the case above, the observation with a higher variance would produce the smaller distance, as desired.

Even using this as a weighting method, it is still possible that we will make an error in data association. From an estimation point of view, this will introduce an outlier in the estimation process with, as discussed above, potentially disastrous results. Another approach, analogous to [IRLS](#), is instead to weight the data based on the distance to a model. This leads naturally to the notion of a *data association filter*. We refer the reader to [\[5.20\]](#) for extensive discussions of these techniques.

5.4.5 Modeling Sensors

To this point, we have introduced several sensing modalities, and we have discussed several methods for estimation. However, the latter often rely on having statistical models for the former. Thus, no chapter on sensing and estimation would be complete without a short discussion of modeling sensors.

Developing a sensor model potentially involves four major elements:

1. Creating a physical model
2. Determining a sensor calibration
3. Determining an error model
4. Identifying failure conditions.

The physical model is the relationship f between the underlying quantities of interest (x) and the available data (y). In many cases, this relationship is obvious, e.g., the distance from a laser sensor to a surface in the world. In others, it may be less so, e.g., what is the right model relating intensities in multiple camera images to the distance to an observed point? In some cases, it may be necessary to include computational processes, e.g., feature detection and correspondence, in the sensor model.

Once a physical model is determined, there is often a process of sensor calibration. Such procedures are typically specific to the sensor in question, for example, the imaging geometry of a perspective camera system requires identification of two scale parameters (governing image scale) and the location of the optical center (two additional parameters). There are also often lens distortion parameters. These parameters can only be determined by a careful calibration procedure [\[5.7\]](#).

Once a calibrated physical sensor model is available, determining an error model typically involves performing an identification of the statistical parameters. Ideally, the first step is to determine an empirical distribution on errors. However, this can often be difficult, as it requires knowing accurate *ground truth* for the underlying unknown parameters. This often requires

the development of a laboratory setup that can simulate the expected sensing situation.

Given such an empirical distribution, there are several important questions, including:

1. Are observations statistically independent?
2. Is the error distribution unimodal?
3. Can the essential aspects of the empirical error be captured using common statistical quantities such as the data variance?

We refer the reader to books on statistics and data modeling [\[5.46\]](#) for further information on this topic.

Finally, it is important to understand when sensors can and cannot provide reliable data, for example, a laser sensor may be less accurate on dark surfaces than on light ones, cameras do not produce meaningful data if the lighting is too bright or too dark, and so forth. In some cases, there are simple clues to these conditions (e.g., simply looking at the intensity histogram of a camera image can quickly determine if conditions are suitable for processing). In some cases it is only possible to detect conditions in context (e.g., two range sensors disagree on the distance to a surface). In some cases failure is only detectable in retrospect, e.g., after a 3-D surface model is built it is apparent that a hypothesized surface would be occluded by another and must therefore be a multiple reflection. In a truly robust sensing system, all available possibilities for verifying sensor operation should be exploited.

5.4.6 Other Uncertainty Management Methods

Due to the limitations of space, we have necessarily limited our discussion to cover the most commonly used sensing and estimation methods. It is important to note that many other alternative uncertainty management methods have been proposed and employed with success.

For example, if it is known that sensing error is bounded, constraint-based methods can be quite effective at performing point estimation [\[5.47, 48\]](#). Alternatively, if only partial probability models can be identified, Dempster-Shafer methods can be employed to make judgments [\[5.49\]](#).

Fuzzy logic allows graded membership of a set. With fuzzy set theory it is possible to have partial membership. As an example in classification of data it might be difficult to select between two categories such as *average* and *tall* and gradual shifts may make sense. Such methods have for example been used for situation assessment and navigation as reported by [\[5.50\]](#) for the DAMN architecture.

5.5 Representations

Sensor data can be used directly for control but it is also used for estimation of the state of the robot and/or the world. The definition of *state* and the appropriate methods for estimation are closely related to the representation adopted for the application.

There are a rich variety of possible world representations including most typical geometric elements such as points, curves, surfaces, and volumes. A fundamental aspect in robotics is the concept of rigid-body *pose*. The pose of a robot or an entity in the world is characterized by position and orientation with respect to a reference frame.

In general, pose is represented by the pair (\mathbf{R}, \mathbf{H}) . Here \mathbf{R} is the orientation of the object represented by a rotation matrix with respect to a reference frame. Similarly, \mathbf{H} represents the translation of the object with respect the reference frame. There is a rich set of potential representations for the transformation between reference frames as detailed in the chapter on Kinematics (Chap. 2) and in [5.51].

Sensory data is acquired in a local sensor reference frame, for example, a sonar transducer, a laser scanner, and a stereo imaging system would all measure distances to surfaces in the world relative to their own frame. However, if the goal is to combine this information into a common world model, the data must be transformed into a robot-centered reference frame, or possibly into a fixed world (inertial) reference frame. In particular, the world-centered reference frame enable simple transfer across robot motions and communication to other robots and/or users.

For the purposes of discussion, most representations for the integration of sensor data can be categorized into four general classes of models:

- Raw sensor data models
- Grid-based models
- Feature-based models
- Symbolic or graphical models.

Naturally, it is also possible to combine elements of these four categories to achieve hybrid models of the environment.

5.5.1 Raw Sensor Representations

For simple feedback control [5.52] it is common to integrate raw sensory data directly into the control system, as in many cases it is unnecessary to have a *world model* for the control. For example, proprioceptive sensing is often used in this manner: basic trajectory control makes direct use of encoder information from joints,

and force control operates directly from force or torque information from force sensors.

Raw sensor models are less common with exteroceptive sensing, but there are cases where it can be useful. One example is mobile robot mapping from dense point data. This approach has in particular been made popular for laser range sensors, where scan alignment is used for the generation of point-based world models. The work by [5.53, 54] demonstrates how a number of laser range scans can be combined into a joint model of the environment. More formally a scan of the environment at time t is represented as a point set

$$\mathcal{P}_t = \{p_i = (\rho_i, \theta_i) | i \in 1 \dots N\}. \quad (5.50)$$

Two different scans \mathcal{P}_t and \mathcal{P}_{t+1} are then aligned through a standard rigid body transformation. The estimation of the transformation is typically achieved through use of the ICP algorithm [5.15]: assume that $\mathbf{H}^{[0]}$ is an initial estimate of the transformation between the two point sets and that $\|\mathbf{p}_t - \mathbf{p}_{t+1}\|$ is the Euclidean distance between a point from \mathcal{P}_t and a point from \mathcal{P}_{t+1} . If furthermore CP is a function to locate the closest point from one set in the other set, then let C be the set of point correspondences between the two sets. Through iterations of the following algorithm,

1. Compute $C_k = \cup_{i=1}^N \{\mathbf{p}_i, CP[\mathbf{H}^{[k-1]}(\mathbf{p}_i, \mathcal{P}_{t+1})]\}$,
2. Estimate the $\mathbf{H}^{[k]}$ that minimizes the LSQ error between the points in C_k until the error has converged

an estimate of the scan alignment can be found and a joint model of the environment can be constructed.

The model is simple to construct and well suited for integration of sensor data from a single modality. Typically the model does not include information about uncertainty and, as the model grows the complexity, $O(\sum_t |\mathcal{P}_t|)$ becomes an issue.

5.5.2 Grid-Based Representations

In a grid-based representation the world is tessellated into a number cells. The cells can contain information about environmental features such as temperature, obstacles, force distribution, etc. The dimensionality of the grid is typically two or three, depending on the application. The tessellation can either be uniform or tree based using quad-tree or oct-trees [5.55]. The tree-based methods are in particular well suited for handling of inhomogeneous and large-scale data sets. In a grid model each cell contains a probability over the parameter set. As an example, when using

the grid model for representation of a physical environment, the cell specifies *occupied* (O) or *free* (F) and the cell encodes the probability $P(\text{occupied})$. Initially where there is no information the grid is initialized to $P(O) = 0.5$ to indicate unknown. It is further assumed that sensor models are available that specify $P(R|S_{ij})$, i.e., the probability of detection objects for a given sensor and location. Using Bayes theorem (5.10) it is now possible to update the grid model according to

$$p_{ij}(t+1) = \frac{P(R|S_{ij} = O)p_{ij}(t)}{P(R|S_{ij} = O)p_{ij}(t) + P(R|S_{ij} = F)(1 - p_{ij}(t))},$$

where p_{ij} is computed across the grid model whenever new data are acquired.

The grid-based model has been widely used in mobile robotics [5.56, 57] and in medical imaging where image volumes are quite common [5.58]. Volume models can be relative large. As an example a millimeter-resolution grid model of the human head requires 4 GB of storage, and thus demands significant computational resources for maintenance.

5.5.3 Feature Representations

Both the raw sensor representation and the grid-based models contain a minimum of abstraction for the sensory data. In many cases there is an interest in extracting features from the sensor data to reduce the storage requirement and only preserve data that are invariant across motion of the platform or external objects. Features span most standard geometric entities such as points (p), lines (l), planes (N, p), curves ($p(s)$), and more general surfaces. For estimation of properties of the external world there is a need for a hybrid model in which collections of features are integrated into a unified model of state.

In general a point is represented in $\mathcal{R}(3)$. Sensors have associated noise and, consequently, in most cases points have an associated uncertainty, typically modeled as Gaussian with mean μ and standard deviation σ . The estimation of the statistics is achieved using first- and second-order moments.

Line features are more difficult to represent. The mathematical line can be represented by the vector pair (p, t), i.e., a point on the line and the tangent vector. In many practical applications the line has a finite extent, and there is a need to encode the length of the line, which can be achieved using end points, start point, tangent, and length. In some cases it is advantageous

Fig. 5.19 A topological map of a spatial environment

to have a redundant representation of the line model to simplify updating and matching. The relation between end-point uncertainties and other line parameters can be derived analytically, as described in [5.59]. The estimation of line parameters is often based on the previously describe RANSAC method through the use of the *Hough* transform [5.10], which is another voting-based method.

For more complex feature models such as curves or surfaces there is a corresponding need to utilize detection methods that facilitate robust segmentation of features, and estimation of the associated uncertainty. A comprehensive description of such methods is available from [5.44].

5.5.4 Symbolic/Graph-Based Models

All of the representations presented in Sects. 5.5.1–5.5.3 are parametric in nature with limited associated semantics. Methods for the recognition of structures, spaces, locations, and objects have seen major recent progress in particular due to advances in statistical learning theory [5.12, 60]. Consequently, today there exist a variety of methods for the recognition of complex structures in sensor data, such as landmarks, road surfaces, body structures, etc. Given the availability of recognized structures it is possible to represent the environment using the previously discussed graphical models. In general a graph is composed of a set of nodes N and a set of edges E that connect nodes. Both nodes and edges can have attributes associated such as labels and distances. One example of a graph structure is a topological map of the environment as shown in Fig. 5.19. The graph representation could also be a semantic model of the environment (objects and places) or a representation of the composition of an object to assembled.

In terms of model updating semantic/graph-based representations can take advantage of recent advances in Bayesian reasoning as presented by *Pearl* [5.61], and exemplified in [5.62].

5.6 Conclusions and Further Readings

Sensing and estimation continues to be a challenging and very active area of robotics research. Several areas of sensing such as computer vision and medical imaging are themselves large and diverse research areas. At the same time, new fundamental and applied techniques in estimation continue to be developed. Indeed, it is fair to say that perception continues to be one of the most challenging areas of robotics research.

Given this wealth of activity, no single chapter can hope to cover all of the material that can be useful in the development of sensor-based robotics. However, the methods that have been presented here are representative of the most commonly used techniques in robotics. In particular, linear techniques such as the Kalman filter continue to form the backbone of perceptive robotics. Part C of the handbook provides more in-depth coverage of several of the key topics in sensing and estimation.

For the reader wishing to learn more, general discussion on the design, physics, and use of a rich variety of sensors can be found in the Handbook of Modern Sensors [5.3]. A discussion of sensors for mobile robots can be found in [5.63], though significant advances have been achieved since the book was published more than a decade ago. Sensing and estimation using computer vision is described in detail in [5.64] and [5.65].

The basic estimation theory is covered in a number of excellent text books. Much of the detection and linear estimation theory is covered in depth in [5.20] and [5.66]. General statistical estimation is covered in [5.12] and [5.13] and the more recently updated version [5.44]. Robust methods are described in detail in [5.21, 43]. In-depth coverage of estimation methods for mobile systems is also covered in [5.33].

6. Model Identification

John Hollerbach, Wisama Khalil, Maxime Gautier

This chapter discusses how to determine the kinematic parameters and the inertial parameters of robot manipulators. Both instances of model identification are cast into a common framework of least-squares parameter estimation, and are shown to have common numerical issues relating to the identifiability of parameters, adequacy of the measurement sets, and numerical robustness. These discussions are generic to any parameter estimation problem, and can be applied in other contexts.

For kinematic calibration, the main aim is to identify the geometric Denavit–Hartenberg (DH) parameters, although joint-based parameters relating to the sensing and transmission elements can also be identified. Endpoint sensing or endpoint constraints can provide equivalent calibration equations. By casting all calibration methods as closed-loop calibration, the calibration index categorizes methods in terms of how many equations per pose are generated.

Inertial parameters may be estimated through the execution of a trajectory while sensing one or more components of force/torque at a joint. Load estimation of a handheld object is simplest because of full mobility and full wrist force–torque sensing. For link inertial parameter estimation, restricted mobility of links nearer the base as well as sensing only the joint torque means that not

all inertial parameters can be identified. Those that can be identified are those that affect joint torque, although they may appear in complicated linear combinations.

6.1 Overview

There are many different kinds of models in robotics, whose accurate identification is required for precise control. Examples from the previous chapters include sensor models, actuator models, kinematic models, dynamic models, and flexibility models. System identi-

cation is the general field concerned with the process of identifying models from measurements. Generally speaking, there are two types of models: parametric and nonparametric models. Parametric models are described by a few parameters, which are adequate to

characterize the accuracy of a model throughout the working range. Examples include sensor gain and offset, the DH parameters for links, and rigid-body inertial parameters. Parametric models are particularly appropriate for robotics, whose components are manmade and whose properties are controlled and understood.

Nonparametric models include the impulse response and the Bode plot for linear systems, and Wiener and Volterra kernels for nonlinear systems [6.1]. A nonparametric model can be used as a stepping stone towards identifying a parametric model; for example, a Bode plot (graph of amplitude and phase versus input frequency) is often used to decide on model order, such as whether an actuator should be modeled as a second- or third-order system. Otherwise, nonparametric models are required when the system's properties are so complicated that a few lumped parameters do not suffice. This is particularly true for biological systems.

This chapter will describe the parametric calibration of the following kinds of models:

1. Kinematic parameters. Kinematic calibration is the process of locating coordinate systems of objects relative to each other. These objects may be isolated from each other, or they may be linked by joints. Examples include:
 - Locating a robot relative to a global reference frame.
 - Locating a stereo vision system relative to a robot.
 - Locating a grasped object relative to the manipulator's gripper frame.
 - Locating neighboring coordinate systems of links of a robot manipulator.
2. Rigid-body inertial parameters. These parameters are required to predict the driving forces and torques to move objects and manipulators.

Suppose there are N_{par} parameters combined into an $N_{\text{par}} \times 1$ parameter vector $\phi = \{\phi_1, \dots, \phi_{N_{\text{par}}}\}$. The parameters may appear linearly or nonlinearly in the model.

$$\text{Linear model:} \quad \mathbf{y}^l = \mathbf{A}^l \phi, \quad (6.1)$$

$$\text{Nonlinear model:} \quad \mathbf{y}^l = f(\mathbf{x}^l, \phi), \quad (6.2)$$

where $\mathbf{y}^l = \{y_1^l, \dots, y_M^l\}$ is the $M \times 1$ vector of output variables and $\mathbf{x}^l = \{x_1^l, \dots, x_n^l\}$ is the vector of input variables. For the linear model, \mathbf{A}^l is an $M \times N_{\text{par}}$ matrix whose entries A_{ij}^l are functions of the input variables \mathbf{x}^l . Any entry A_{ij}^l may be a complicated nonlinear function of \mathbf{x}^l , but it evaluates to just a number. For the nonlinear model, an explicit equation is shown in which

the input variables appear in a nonlinear function $f = \{f_1, \dots, f_M\}$. Implicit nonlinear models $f(\mathbf{y}^l, \mathbf{x}^l, \phi) = \mathbf{0}$ may also appear in calibration [6.2]; they are handled similarly to explicit nonlinear models (Sect. 6.2.2). There may be P different measurements; a particular measurement is indicated by the superscript $l = 1, \dots, P$.

For linear models, information from different measurements is combined by stacking the P (6.1)

$$\mathbf{y} = \mathbf{A}\phi, \quad (6.3)$$

where $\mathbf{y} = \{\mathbf{y}^1, \dots, \mathbf{y}^P\}$ is an $MP \times 1$ vector of all output measurements and $\mathbf{A} = \{\mathbf{A}^1, \dots, \mathbf{A}^P\}$ is $MP \times N_{\text{par}}$. The parameters are estimated by ordinary least squares

$$\phi = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{y}. \quad (6.4)$$

In statistics, the matrix \mathbf{A} is called the regressor matrix and the least-squares solution is called regression [6.3]. An example of a linear model is the rigid-body model for inertial parameters.

The Gauss–Newton method [6.3] is typically employed to estimate the nonlinear model (6.2). First, absorb the input variables \mathbf{x}^l (which can be considered as a number of constants) into the nonlinear function f^l , now given a superscript. The model is linearized through a Taylor series expansion at a current estimate ϕ^k of the parameters at iteration k

$$\begin{aligned} \mathbf{y}_c^l &= f^l(\phi^k + \Delta\phi) \\ &= f^l(\phi^k) + \left. \frac{\partial f^l(\phi)}{\partial \phi} \right|_{\phi=\phi^k} \Delta\phi \\ &\quad + \text{higher order terms} \\ &\approx f^l(\phi^k) + \mathbf{A}^l \Delta\phi, \end{aligned} \quad (6.5)$$

where \mathbf{y}_c^l are the computed values of the output variables and $\mathbf{A}^l = \partial f^l / \partial \phi$ is a Jacobian matrix evaluated at ϕ^k . Higher-order terms in the Taylor series are ignored, yielding the linearized form (6.5). The bold assumption is now made that a correction $\Delta\phi$ to the parameter estimate ϕ^k causes the computed output variables to equal the measurements: $\mathbf{y}_c^l = \mathbf{y}^l$. Defining $\Delta\mathbf{y}^l = \mathbf{y}^l - f^l(\phi^k)$ as the error between the output measurement and the predicted output with the current model ϕ^k , the linearized (6.5) becomes

$$\Delta\mathbf{y}^l = \mathbf{A}^l \Delta\phi. \quad (6.6)$$

The linearized equation is then stacked for P measurements for the estimation form

$$\Delta\mathbf{y} = \mathbf{A} \Delta\phi. \quad (6.7)$$

A correction $\Delta\phi$ to the parameter estimates is now found by ordinary least squares

$$\Delta\phi = (\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}^T\Delta\mathbf{y}. \quad (6.8)$$

This process is iterated with a new estimate $\phi^{k+1} = \phi^k + \Delta\phi$ until the error $\Delta\phi$ becomes sufficiently small. The Gauss–Newton method has quadratic convergence, which is very fast, provided that there is a good initial estimate ϕ^0 of the parameters and the nonlinearity is not too severe. An example of a nonlinear model is the kinematic model containing the DH parameters. The nonlinearity is mild because it is due to sines and cosines, so the Gauss–Newton method usually has good convergence properties.

Both for linear and nonlinear estimation, however, rank deficiencies and numerical ill-conditioning may cause problems in inverting $\mathbf{A}^T\mathbf{A}$. Rank deficiencies may result from two problems:

1. Inadequate data. The quality of the data for estimating the parameters can be quantified by an observability index, such as the condition number [6.4] of the regressor matrix \mathbf{A} . A different choice of data to maximize the observability index might result in more robust estimates. Examples are choosing different poses for kinematic calibration, or different trajectories for inertial parameter estimation.
2. Unidentifiable parameters. Perhaps no set of data from an experiment can identify some of the parameters. A procedure has to be found to eliminate or circumvent the unidentifiable parameters. Parameter elimination is usually done by using the singular value decomposition of \mathbf{A} , while circumvention can be achieved by using a priori values and ridge re-

gression. This does not mean that the parameters are intrinsically identifiable, only that the experimental setup precludes their determination; for example, only one of the 10 inertial parameters of the first link of a robot manipulator can be identified if the base of the manipulator is stationary. A different experimental setup involving accelerating the base of the manipulator and measuring the reaction forces and torques at the base would allow other parameters to be identified [6.5].

Ill-conditioning may result from poor scaling of measurements or parameters:

1. The least-squares estimation minimizes the error between the predicted and measured output vector. Components y_j^l of the output vector \mathbf{y}^l may have different units and magnitudes, such as radians versus meters, in pose measurements for kinematic calibration. Moreover, not all components may be measured to the same level of accuracy. Normalizing the output vectors with an appropriately chosen weighting matrix may result in a better conditioned estimate.
2. The parameters may also have different units and different magnitudes. This can cause problems both in terms of convergence criteria and in terms of deciding which parameters to eliminate. Again, a weighting matrix for the parameters may be introduced to improve the conditioning.

These numerical issues are generic to any parameter estimation problem, and are discussed at the end of this chapter. The next sections discuss individual robot models and issues in putting them into parameter estimation form.

6.2 Kinematic Calibration

In general, the relative location between coordinate systems requires six geometric parameters to be calibrated (position plus orientation). If there are mechanical constraints between the relative movement of the coordinate systems, such as connection by a joint, fewer parameters are required. For a rotary joint connecting two links, whose axis is a line-bound vector, four geometric parameters are required. For a prismatic joint, whose axis is a free vector, only two geometric parameters describing orientation are required.

In addition, nongeometric parameters are required to model sensors and mechanical deflection:

- Joint angle sensors may require a gain and offset determination.
- Camera calibration using an undistorted pinhole camera model may require the determination of the focal length and an image sensor offset.
- Joint flexibility from gears leads to angle change due to gravity loading and the manipulator's own weight.
- Base flexibility results from nonrigid attachment of the robot to the environment. Depending on how the manipulator is outstretched, there will be a varying effect on endpoint location.

- Thermal effects and vibration may need to be modeled for very fine positioning control.

This section focuses on determining the geometric parameters and the sensor-based nongeometric parameters.

6.2.1 Serial-Link Robot Manipulators

The modified Denavit–Hartenberg (DH) parameters (Fig. 6.1) serve as the main geometric parameters (Sect. 2.4); the link transformation matrix is

$${}^{i-1}\mathbf{T}_i = \text{Rot}(\mathbf{x}, \alpha_i) \text{Trans}(\mathbf{x}, a_i) \text{Trans}(\mathbf{z}, d_i) \text{Rot}(\mathbf{z}, \theta_i). \quad (6.9)$$

- For an n -joint manipulator with rotary joint $i = 1, \dots, n$, whose axis \mathbf{z}_i is a line in space, all four parameters a_i , d_i , α_i , and θ_i have to be calibrated.
- For a prismatic joint i , whose axis \mathbf{z}_i is a free vector, only two parameters describing its orientation (α_i and θ_i) are required. In principle, the axis \mathbf{z}_i can be positioned anywhere in space. This means two DH parameters are arbitrary. One possibility is to intersect \mathbf{z}_i with O_{i+1} [6.6, 7], which sets $d_{i+1} = 0$ and $a_{i+1} = 0$. While kinematically correct, this placement is nonintuitive in that it doesn't correspond to the physical location of the prismatic mechanism. It is possible to set a_{i+1} with a_i or θ_i to values that position \mathbf{z}_i in the middle of the prismatic joint's mechanical structure.

In the case of nearly parallel neighboring axes, the common normal is poorly defined and the calibration is ill-conditioned. For this case, Hayati and Mirmirani [6.7] introduced an extra rotational parameter β_i about the \mathbf{y}_{i-1} axis (Fig. 6.2).

Let \mathbf{x}'_{i-1} lie along a line from O_i to axis \mathbf{z}_{i-1} , such that \mathbf{x}'_{i-1} is perpendicular to \mathbf{z}_i ; the intersection point

Fig. 6.1 The modified DH parameters

defines the origin O_{i-1} . Two rotations are required to relate \mathbf{z}_{i-1} to $\mathbf{z}_i = \mathbf{z}'_{i-1}$: a rotation α_i about \mathbf{x}'_{i-1} maps \mathbf{z}'_{i-1} to \mathbf{z}_i , and a rotation β_i about $\mathbf{y}_{i-1} = \mathbf{y}'_{i-1}$ maps \mathbf{z}_{i-1} to \mathbf{z}'_{i-1} . The angle θ_i is now from \mathbf{x}'_{i-1} to \mathbf{x}_i about \mathbf{z}_i . The link transformation is

$${}^{i-1}\mathbf{T}_i = \text{Rot}(\mathbf{y}, \beta_i) \text{Rot}(\mathbf{x}, \alpha_i) \text{Trans}(\mathbf{x}, a_i) \text{Rot}(\mathbf{z}, \theta_i). \quad (6.10)$$

- For a rotary joint, the parameter β_i is calibrated instead of d_i .
- For a prismatic joint, the joint variable d_i has to be retained. As before, position \mathbf{z}_i at some convenient location on link i , by specifying two parameters relative to the coordinate system $i + 1$. Then proceed with the construction of the Hayati parameters for $d_i = 0$. As d_i changes, axis \mathbf{x}_i is displaced along \mathbf{z}_i relative to \mathbf{x}'_{i-1} (not shown). The link transformation is

$${}^{i-1}\mathbf{T}_i = \text{Rot}(\mathbf{y}, \beta_i) \text{Rot}(\mathbf{x}, \alpha_i) \text{Trans}(\mathbf{x}, a_i) \text{Trans}(\mathbf{z}, d_i) \text{Rot}(\mathbf{z}, \theta_i). \quad (6.11)$$

Although there are five parameters in this transformation, the process of setting the Hayati parameters for $d_i = 0$ is tantamount to setting the value of d_{i-1} to locate O_{i-1} , so there is no net increase in the number of parameters.

The procedures above set the coordinate systems in the intermediate links of a serial manipulator. Coordinate systems also have to be set in the base and end links, but the procedure for doing so depends on the external metrology system and on any physical constraints on the end link pose. The last frame may be n or $n + 1$, while the first frame may be 0 or -1 (to keep consecutive numbers); examples appear below. Collect the unknown kinematic parameters into the vectors \mathbf{a} , \mathbf{d} , $\boldsymbol{\alpha}$, $\boldsymbol{\theta}$, and $\boldsymbol{\beta}$, and thence into the parameter vector $\boldsymbol{\phi} = \{\mathbf{a}, \mathbf{d}, \boldsymbol{\alpha}, \boldsymbol{\theta}, \boldsymbol{\beta}\}$. The parameters $\boldsymbol{\phi}$ predict the

Fig. 6.2 The additional parameter β_i about \mathbf{y}_{i-1} is employed for nearly parallel axes

position and orientation of the last coordinate system relative to the first, such as ${}^0T_{n,c}$.

Not all six components of pose are necessarily used for calibration; the number can vary from one to six. Calibration proceeds by observing the error in the prediction of a certain number of pose components, then employing the nonlinear calibration method (6.7). There are two general methods for observing error:

- *Open-loop calibration* utilizes an external metrology system to measure the pose components. Because the manipulator is not in contact with the environment during this process, the method is termed open loop.
- *Closed-loop calibration* utilizes physical constraints on the end link pose to substitute for measurements. Deviations from the physical constraint represent the prediction error. Because of the contact with the physical constraint, the manipulator forms a closed loop with the ground.

Open-Loop Kinematic Calibration

The calibration literature contains a variety of metrology systems, which can be categorized based on the number of pose components measured [6.8]:

- *1 component:* The distance to a single point on the end link can be measured in a variety of ways, such as an instrumented ball bar [6.9], wire potentiometer [6.10], or laser displacement meter [6.11].
- *2 components:* A single theodolite has been employed to provide two orientation measurements [6.12]. A reference length had to be sighted for scaling.
- *3 components:* Laser tracking systems provide accurate three-dimensional (3-D) measurements by reflecting a beam off a retroreflector mounted on the end effector. The beam provides length information, while the gimbal drive for laser steering provides two orientation measurements [6.13]. Since the least precise part of this setup is the angle sensing, another approach is to employ three laser tracking systems and use only the length information. Commercial 3-D stereo-camera motion tracking systems also provide high-accuracy measurements of position.
- *5 components:* Lau et al. [6.14] presented a steerable laser interferometer with steerable reflector. With pitch and yaw measurements, the steerable interferometer yields all three components of position, while the steerable reflector yields two components of orientation.
- *6 components:* Full pose can be inferred from the 3-D position of multiple points on the last link measured with a stereo-camera system. A coordinate system fit to the cloud of points yields position plus orientation [6.15]. Vincze et al. [6.16] measured full pose with a single-beam laser tracking system, by fitting the robot with a retroreflector mounted on a universal joint. Position is measured using interferometry, as usual. The novel aspect is orientation measurement, by imaging of the diffraction pattern of the edges of the retroreflector.

Examples are given for calibrating with three pose components and with all six pose components measured.

Point Measurement. The 3-D position of a particular point on the end link can be conveniently located by some form of stereo camera system. The camera system defines a global coordinate system relative to which frame 1 of the robot is located. To provide enough parameters, an intermediate coordinate system has to be introduced; this intermediate coordinate system has index 0, while the camera system is given index -1 to keep consecutive numbers. Two of the eight parameters are arbitrary. Figure 6.3 shows one possibility: z_0 is made parallel ($\alpha_0 = 0$) and coincident ($a_0 = 0$) with z_{-1} . The calibrated parameters are d_0 , θ_0 , a_1 , d_1 , α_1 , and θ_1 . In the case that z_{-1} is nearly parallel to z_0 , the measurement coordinate system can be simply redefined to avoid using Hayati parameters; for example, y_{-1} can be redefined as z_{-1} .

In the end link, the origin O_n and axis x_n are unspecified, as are the associated parameters d_n and θ_n . Locating the measured point requires only three parameters, so the addition of a single coordinate system $n + 1$ is required to provide an additional parameter.

Fig. 6.3 A camera system (index -1) is located relative to the manipulator coordinate system 1 via an intermediate coordinate system 0

The measured point is defined as the origin O_{n+1} of the new coordinate system, and the normal from z_n that intersects O_{n+1} defines the x_n axis (Fig. 6.4). Three parameters are arbitrary; a simple choice is to make z_{n+1} parallel to z_n ($\alpha_{n+1} = 0$) and x_{n+1} collinear with x_n ($\theta_{n+1} = 0$ and $d_{n+1} = 0$). The calibrated parameters are a_{n+1} , d_n , and θ_n .

From the transformation

$${}^{-1}\mathbf{T}_{n+1} = {}^{-1}\mathbf{T}_0 \dots {}^n\mathbf{T}_{n+1},$$

the position ${}^{-1}\mathbf{p}_{n+1}$ of the measured point relative to the camera frame is extracted. Collect the unknown kinematic parameters into vectors \mathbf{a} , \mathbf{d} , $\boldsymbol{\alpha}$, $\boldsymbol{\theta}$, and $\boldsymbol{\beta}$, and thence into the parameter vector $\boldsymbol{\phi} = \{\mathbf{a}, \mathbf{d}, \boldsymbol{\alpha}, \boldsymbol{\theta}, \boldsymbol{\beta}\}$. The nonlinear kinematic model analogous to (6.2) is

$${}^{-1}\mathbf{p}_{n+1}^l = f(\mathbf{q}^l, \boldsymbol{\phi}), \quad l = 1, \dots, P, \quad (6.12)$$

where \mathbf{q}^l is the vector of joint variables for pose l . To linearize this equation into estimation form (6.6), the associated Jacobians for each parameter type are calcu-

Fig. 6.4 A measured point O_{n+1} is located on the end link by adding a coordinate system $n + 1$

Fig. 6.5 Full pose measurement of coordinate system $n + 1$ in the end link

lated

$$\begin{aligned} \Delta {}^{-1}\mathbf{p}_{n+1}^l &= {}^{-1}\mathbf{p}_{n+1}^l - {}^{-1}\mathbf{p}_{n+1,c}^l = \mathbf{J}^l \Delta \boldsymbol{\phi} \\ &= (\mathbf{J}_a^l \quad \mathbf{J}_d^l \quad \mathbf{J}_\alpha^l \quad \mathbf{J}_\theta^l \quad \mathbf{J}_\beta^l) \begin{pmatrix} \Delta \mathbf{a} \\ \Delta \mathbf{d} \\ \Delta \boldsymbol{\alpha} \\ \Delta \boldsymbol{\theta} \\ \Delta \boldsymbol{\beta} \end{pmatrix}, \end{aligned} \quad (6.13)$$

where a typical column i for each individual parameter Jacobian is derived from the screw parameters as if each parameter represented an active joint (Sect. 2.8.1)

$$\mathbf{J}_{a_i}^l = \begin{cases} {}^{-1}\mathbf{x}_{i-1}^l & \text{DH} \\ {}^{-1}\mathbf{x}_{i-1}^l & \text{Hayati} \end{cases}, \quad (6.14)$$

$$\mathbf{J}_{d_i}^l = {}^{-1}\mathbf{z}_i^l, \quad (6.15)$$

$$\mathbf{J}_{\alpha_i}^l = \begin{cases} {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l & \text{DH} \\ {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l & \text{Hayati} \end{cases}, \quad (6.16)$$

$$\mathbf{J}_{\theta_i}^l = {}^{-1}\mathbf{z}_i^l \times {}^{-1}\mathbf{d}_{i,n+1}^l, \quad (6.17)$$

$$\mathbf{J}_{\beta_i}^l = {}^{-1}\mathbf{y}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l, \quad (6.18)$$

where ${}^{-1}\mathbf{d}_{i,n+1}^l = {}^{-1}\mathbf{R}_i^l \mathbf{p}_{n+1}$ refers the interorigin vector to coordinate system -1 . Equation (6.13) is stacked for all the poses for the final estimation form

$$\Delta {}^{-1}\mathbf{p}_{n+1} = \mathbf{J} \Delta \boldsymbol{\phi}, \quad (6.19)$$

which corresponds to (6.7) and which is solved for $\Delta \boldsymbol{\phi}$ by least squares and for $\boldsymbol{\phi}$ by iteration.

Full Pose Measurement. Suppose that coordinate system $n + 1$ in link n is measured (Fig. 6.5). Coordinate system n is completed in the usual way, and the six calibrated parameters to locate coordinate system $n + 1$ are d_n , α_n , θ_n , a_{n+1} , d_{n+1} , and θ_{n+1} . If z_{n+1} is nearly parallel to z_n , this axis may simply be permuted with other axes, such as y_{n+1} , to avoid using the Hayati parameters.

In addition to the position (6.12), orientation equations of coordinate system $n + 1$

$${}^{-1}\mathbf{R}_{n+1}^l = \mathbf{F}(\mathbf{q}^l, \boldsymbol{\phi}), \quad l = 1, \dots, P \quad (6.20)$$

are extracted from ${}^{-1}\mathbf{T}_{n+1}$, where \mathbf{F} is a matrix function. Linearization of this equation yields

$$\begin{aligned} \Delta {}^{-1}\mathbf{R}_{n+1}^l &= {}^{-1}\mathbf{R}_{n+1}^l - {}^{-1}\mathbf{R}_{n+1,c}^l \\ &= \Delta {}^{-1}\boldsymbol{\rho}_{n+1}^l \times {}^{-1}\mathbf{R}_{n+1,c}^l \end{aligned}$$

$$\mathbf{S}(\Delta {}^{-1}\boldsymbol{\rho}_{n+1}^l) = ({}^{-1}\mathbf{R}_{n+1}^l - {}^{-1}\mathbf{R}_{n+1,c}^l) ({}^{-1}\mathbf{R}_{n+1,c}^l)^T, \quad (6.21)$$

where $\Delta^{-1}\rho_{n+1}^l$ are differential orthogonal rotations which are the finite-difference counterpart to the angular velocity vector. Continuing with this analogy, a Jacobian \mathbf{J} similar to that for spatial velocities (Sect. 2.8.1) is employed to represent the combined effect of parameter variations $\Delta\phi$ on changes in position $\Delta^{-1}\mathbf{p}_{n+1}^l$ and orientation $\Delta^{-1}\rho_{n+1}^l$

$$\begin{pmatrix} \Delta^{-1}\mathbf{p}_{n+1}^l \\ \Delta^{-1}\rho_{n+1}^l \end{pmatrix} = \mathbf{J}^l \Delta\phi. \quad (6.22)$$

Compared to (6.13), the Jacobian \mathbf{J}^l now has six rows, as do the individual parameter Jacobians

$$\mathbf{J}_{a_i}^l = \begin{cases} \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \\ \mathbf{0} \end{pmatrix} & \text{DH} \\ \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \\ \mathbf{0} \end{pmatrix} & \text{Hayati} \end{cases}, \quad (6.23)$$

$$\mathbf{J}_{d_i}^l = \begin{pmatrix} {}^{-1}\mathbf{z}_i^l \\ \mathbf{0} \end{pmatrix}, \quad (6.24)$$

$$\mathbf{J}_{\alpha_i}^l = \begin{cases} \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{x}_{i-1}^l \end{pmatrix} & \text{DH} \\ \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{x}_{i-1}^l \end{pmatrix} & \text{Hayati} \end{cases}, \quad (6.25)$$

$$\mathbf{J}_{\theta_i}^l = \begin{pmatrix} {}^{-1}\mathbf{z}_i^l \times {}^{-1}\mathbf{d}_{i,n+1}^l \\ {}^{-1}\mathbf{z}_i^l \end{pmatrix}, \quad (6.26)$$

$$\mathbf{J}_{\beta_i}^l = \begin{pmatrix} {}^{-1}\mathbf{y}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{y}_{i-1}^l \end{pmatrix}. \quad (6.27)$$

As before, $\Delta\phi$ is found by least squares and ϕ by iteration.

Closed-Loop Calibration

Physical constraints on end-effector position or orientation can substitute for measurements. The location of a physical constraint defines the reference coordinate system; the *measurement* of endpoint position or orientation is therefore defined as zero. The deviation from the physical constraint due to an incorrect kinematic model is cast as a displacement from the reference coordinates. Analogous to point measurement and full pose measurement, there are closed-loop methods using point constraints and full pose constraints.

Point Constraint. Suppose that the end-effector holds a stylus that makes contact with a fixed point in the environment. The orientation of the stylus can be changed

by varying the joint angles, as long as the point of contact is not changed. Before, the measurement system for point measurement defined the reference coordinate system -1 (Fig. 6.3), and there was an end effector coordinate system $n+1$ whose origin O_{n+1} was measured (Fig. 6.4). Now the reference coordinate origin O_0 has index 0 and is collocated with O_{n+1} (Fig. 6.6). An extra coordinate system -1 is not required because a point is located relative to coordinate system 1 with only three parameters: a_1 , d_1 , and θ_1 . The arbitrary choice $\alpha_1 = 0$ is made, i. e., \mathbf{z}_0 is made parallel to \mathbf{z}_1 .

Different poses while maintaining the point contact can be generated manually, or they can be generated automatically if there is a force control capability. In comparison to (6.13), the *measured* position ${}^0\mathbf{p}_{n+1}^l = \mathbf{0}$ by definition and the linearized calibration equation is simply

$$\Delta^{-1}\mathbf{p}_{n+1}^l = -{}^{-1}\mathbf{p}_{n+1,c}^l = \mathbf{J}^l \Delta\phi. \quad (6.28)$$

The set of poses that may be generated is limited relative to open-loop calibration, which may affect identifiability.

Full Pose Constraint. Analogous to full pose measurement (Fig. 6.5), the end link may be fully constrained by rigidly gripping the environment. If the manipulator is redundant (Chap. 10), then poses can be generated through self motion. Generating such poses would require endpoint force/torque sensing or joint torque sensing to be accomplished.

The end link can be considered part of the ground due to rigid attachment, and therefore one fewer coordinate system is required than for the fixed point case. Fig. 6.7 shows one way of setting up coordinate systems 0 and n for calibration. Axis \mathbf{z}_0 is set equal and coincident with axis \mathbf{z}_n . The common normal between \mathbf{z}_0 and \mathbf{z}_1 sets the origin O_0 and the axis \mathbf{x}_0 . Coordinate system n is completed by defining $O_n = O_0$ and $\mathbf{x}_n = \mathbf{x}_0$. Six parameters result for calibration, as they must to re-

Fig. 6.6 Fixed point contact, setting $O_0 = O_{n+1}$

late coordinate system n to coordinate system 0: θ_n , d_n , α_1 , a_1 , d_1 , and θ_1 .

Similar to (6.28) after index adjustment, the *measured* position ${}^0\mathbf{p}_n^l = \mathbf{0}$ by definition and the linearized position calibration equation is

$$\Delta {}^0\mathbf{p}_n^l = -{}^0\mathbf{p}_{n,c}^l. \quad (6.29)$$

With regard to the error in orientation (6.21), the *measured* orientation ${}^0\mathbf{R}_n^l = \mathbf{I}$, the identity matrix, after index adjustment.

$$\mathbf{S}(\Delta {}^0\mathbf{p}_n^l) = (\mathbf{I} - {}^0\mathbf{R}_{n,c}^l) ({}^0\mathbf{R}_{n,c}^l)^T = ({}^0\mathbf{R}_{n,c}^l)^T - \mathbf{I}. \quad (6.30)$$

The error (6.22) is then applied as for full pose measurement, after index adjustment. The set of poses that may be generated is limited relative to open-loop calibration, which may affect identifiability.

6.2.2 Parallel Manipulator Calibration

Parallel manipulators are comprised of multiple closed loops. The methods of the previous section could readily be extended to calibrate parallel manipulators. Rather than treat parallel and serial manipulators differently, and continue to elaborate the calibration equations on a case-by-case basis that includes different loop arrangements and different sensing arrangements, *Hollerbach* and *Wampler* [6.8] presented a unifying methodology termed the *calibration index*, which views all calibration problems as closed-loop calibration problems.

Open-loop calibration is converted to closed-loop calibration by considering the end effector measurement to form a joint. All measurements, whether from joints or metrology systems, are put on an equal footing, as are all unsensed joints, whether from unsensed

components of pose, passive environmental constraints, or joints in the chain without sensors. In the case of parallel linkages, sufficient numbers of loop-closure equations are formulated to characterize the kinematics and are combined at each pose. Because the loop-closure equations are implicit functions of all measurements, *Wampler* et al. [6.2] called this calibration method the *implicit loop method*.

Fig. 6.8 illustrates this idea for a calibrated stereo camera metrology system that measures the 3-D coordinates of a distinguished point on the end-effector of an uncalibrated robot. On the right this camera system has been replaced by a prismatic leg, which stylistically represents a six-degree-of-freedom (6-DOF) joint that provides equivalent 3-D coordinate measurements. The result is a closed-loop mechanism.

The kinematic loop closure equations \mathbf{f} for the i -th pose ($i = 1, \dots, P$) are formed as

$$\mathbf{f}^i(\boldsymbol{\phi}) \equiv \mathbf{f}(\mathbf{x}^i, \boldsymbol{\phi}) = \mathbf{0}, \quad (6.31)$$

where $\boldsymbol{\phi}$ is a vector of robot parameters to be calibrated, \mathbf{x}^i is a vector of joint sensor readings and possibly external sensor readings, and \mathbf{f}^i absorbs the sensor readings \mathbf{x}^i and so is given an index. Combining (6.31) for the P poses into a single matrix equation

$$\mathbf{f}(\boldsymbol{\phi}) = \begin{pmatrix} \mathbf{f}^1{}^T & \dots & \mathbf{f}^P{}^T \end{pmatrix}^T = \mathbf{0}. \quad (6.32)$$

Linearize (6.32) around the nominal values of the parameters

$$\Delta \mathbf{f} = \frac{\partial \mathbf{f}}{\partial \boldsymbol{\phi}} \Delta \boldsymbol{\phi} = \mathbf{A} \Delta \boldsymbol{\phi}, \quad (6.33)$$

where $\Delta \mathbf{f}$ is the deviation of the computed loop closure equations from zero, \mathbf{J} is the identification Jacobian, and $\Delta \boldsymbol{\phi}$ is the correction to be applied to the current parameter estimate. The calibration problem is then solved by minimizing $\Delta \mathbf{f}$ via iterative least squares.

Fig. 6.7 Fully constrained end link, setting $O_0 = O_n$

Fig. 6.8 External metrology system modeled as a 6-DOF joint

The Calibration Index

The basis for kinematic calibration is to compute the error in positioning a manipulator using the current kinematic model. The error may be relative to measurements by an external metrology system (open-loop methods), or relative to a physical constraint such as contact with a plane (closed-loop methods). An external metrology system may measure all six components of pose or fewer components such as a point on the end link (three components). Likewise, a physical constraint can limit between one and six components of pose. Constraints and measurements may be mixed. The number of measurements and constraints determine how many scalar equations per pose are available for calibration.

The calibration index C quantifies the number of equations per pose. While this analysis is rather straightforward for serial linkages, for parallel linkages it can be difficult to infer the number of independent equations per pose

$$C = S - M, \quad (6.34)$$

where S is the sensor index and M is the mobility index. The mobility index [6.17] characterizes the degrees of freedom in the calibration setup.

$$M = 6n - \sum_{i=1}^{N_J} n_i^c, \quad (6.35)$$

where n is the number of links, N_J is the number of joints, and n_i^c is the number of constraints at joint i . n includes any extra links attached to the robot to constrain or measure its motion. N_J includes joints of any additional linkages added for calibration. For a rotational or prismatic joint $n_i^c = 5$, while for a ball or spherical joint $n_i^c = 3$. For an external measurement system for a freely moving end-effector $n_{N_J}^c = 0$, while for rigid attachment of the endpoint $n_{N_J}^c = 6$. While generally correct, there are exceptions to (6.35) due to special or degenerate mechanisms that have to be analyzed on a case-by-case basis.

The sensor index S is the total number of sensors in the joints

$$S = \sum_{i=1}^{N_J} S_i, \quad (6.36)$$

where S_i is the number of sensed degrees in joint i . Usually $S_i = 1$ for the lower-order pairs typical of actuated joints, while $S_{N_J} = 6$ for full pose measurement of the end-effector joint N_J . For an unsensed joint, such as in passive environment kinematics, $S_i = 0$.

If P is the number of poses, then CP is the total number of equations for the calibration procedure. Clearly a larger C means that fewer poses are required, other things being equal. For the single-loop case consisting of a series of sensed lower-order robot joints ($S_i = 1$, $n_i^c = 5$, $i = 1, \dots, N_J - 1$) with a final joint ($S_{N_J}, n_{N_J}^c$) connecting the end-effector to ground, one has from (6.34–6.35)

$$C = S_{N_J} + n_{N_J}^c. \quad (6.37)$$

According to the calibration index, using full endpoint constraints is an equivalent kinematic calibration method to using full pose measurements. There is potentially a problem with the smaller range of poses available with the endpoint constrained, but otherwise the mathematics are the same.

Categorization of Serial Link Calibration Methods

A great variety of calibration methods have been proposed, varying in the manner of pose measurement or endpoint constraints. These are categorized below according to the calibration index C and the values of $n_{N_J}^c$ and S_{N_J} :

- $C = 6$: $n_{N_J}^c = 0$ and $S_{N_J} = 6$ corresponds to full pose measurement. $n_{N_J}^c = 6$ and $S_{N_J} = 0$ corresponds to rigid endpoint attachment.
- $C = 5$: $n_{N_J}^c = 0$ and $S_{N_J} = 5$ corresponds to 5-DOF pose measurement [6.14]. $n_{N_J}^c = 5$ and $S_{N_J} = 0$ corresponds to 5-DOF endpoint constraints, such as manipulation of an unsensed passive hinge joint [6.18].
- $C = 4$: No published method exists for $C = 4$.
- $C = 3$: $n_{N_J}^c = 0$ and $S_{N_J} = 3$ corresponds to 3-DOF pose measurement. $n_{N_J}^c = 3$ and $S_{N_J} = 0$ corresponds to 3-DOF endpoint constraints.
- $C = 2$: $n_{N_J}^c = 0$ and $S_{N_J} = 2$ corresponds to 2-DOF pose measurements, such as is provided by a single theodolite [6.12]. $n_{N_J}^c = 2$ and $S_{N_J} = 0$ corresponds to 2-DOF endpoint constraints. Motion along a line provides two constraints [6.19].
- $C = 1$: $n_{N_J}^c = 0$ and $S_{N_J} = 1$ corresponds to measurement of just 1-DOF pose, provided by a linear transducer such as an linear variable differential transformer (LVDT) [6.9] or wire potentiometer [6.10]. $n_{N_J}^c = 1$ and $S_{N_J} = 0$ corresponds to a plane constraint [6.20].

Categorization of Parallel-Link Calibration Methods

To calibrate parallel robots, a loop-closure equation is written for each loop j

$$\mathbf{0} = \mathbf{f}_j(\boldsymbol{\phi}). \quad (6.38)$$

The equations for all the loops are combined. One problem is to eliminate unsensed degrees of freedom. The calibration index is now applied based on the number of loops:

- **2 loops:** A two-loop mechanism has three arms or legs, attached to a common platform. An example is the RSI Research Ltd. Hand Controller [6.21], which employs three 6-DOF arms with three sensed joints each. The mobility of this mechanism is $M = 6$. As $S = 9$, therefore $C = 3$ and closed-loop calibration is possible.
- **4 loops:** Nahvi et al. [6.22] calibrated a spherical shoulder joint, driven redundantly by four prismatic legs (Fig. 6.9). In addition, the platform is constrained to rotate about a spherical joint; with the four legs, four kinematic loops are formed. For this system, $M = 3$ and $S = 4$, so that $C = 1$. Hence self-calibration is possible. Without the extra leg and the sensing it provides, one would have $C = 0$ and calibration would not be possible.
- **5 loops:** Wampler et al. [6.2] calibrated the six-legged Stewart platform ($M = 6$) via a closed-loop

Fig. 6.9 Redundant parallel drive shoulder joint

procedure. In addition to leg length measurements, all angles on one of the legs were measured ($S = 11$). The reason for the extra sensors is to yield a unique forward kinematics solution, but a side benefit is that, with $C = 5$, closed-loop calibration is possible. For a regular Stewart platform without the instrumented leg, $S = 6$ and hence $C = 0$. External pose measurement is required; for example, with full pose measurement $S = 12$ and $C = 6$; full pose measurement was utilized in [6.23].

6.3 Inertial Parameter Estimation

A rigid body i has 10 inertial parameters: mass m_i , center of mass r_{0i} relative to an origin O_0 , and symmetric inertia matrix \bar{I}_i referred here to the origin O_i (Fig. 6.10). The rigid body may be a load held by the end effector, or it can be one of the manipulator's own links. By generating a trajectory and measuring forces or torques in combination with velocity and acceleration, some or all of the inertial parameters can be estimated.

6.3.1 Link Inertial Parameter Estimation

The procedure involves:

1. Formulating the Newton–Euler equations of the load dynamics to reveal a linear dependence on the inertial parameters.
2. Estimating the parameters using ordinary least squares.

Begin with the Newton–Euler equations of the last link, and assume that suitable filters have been designed to estimate the velocity $\dot{\theta}_i$ and acceleration $\ddot{\theta}_i$ at each joint i .

The center of mass of link n is defined as C_n , located relative to the base origin O_0 by $r_n = C_n - O_0$ and

relative to link n 's origin O_n by $c_n = C_n - O_n$. All vectors and matrices are expressed in coordinate system n , in which the center of mass location c_n and the inertia matrix \bar{I}_n about origin O_n are constant.

From (3.35) in Chap. 3, the Newton–Euler equations referred to O_n are

$$f_n = I_n a_n + v_n \times I_n v_n. \quad (6.39)$$

Substituting for the spatial inertia I_n , the spatial acceleration a_n , and the spatial velocity v_n , the first term on

Fig. 6.10 Location of the center of gravity for an intermediate link i , and the constraint forces and torques

the right evaluates to

$$\begin{aligned} \mathbf{I}_n \mathbf{a}_n &= \begin{pmatrix} \bar{\mathbf{I}}_n & m_n \mathbf{S}(\mathbf{c}_n) \\ m_n \mathbf{S}(\mathbf{c}_n)^T & m_n \mathbf{1} \end{pmatrix} \begin{pmatrix} \dot{\omega}_n \\ \dot{\mathbf{v}}_n \end{pmatrix} \\ &= \begin{pmatrix} \bar{\mathbf{I}}_n \dot{\omega}_n + m_n \mathbf{S}(\mathbf{c}_n) (\ddot{\mathbf{d}}_{0n} - \omega_n \times \mathbf{v}_n) \\ m_n \mathbf{S}(\mathbf{c}_n)^T \dot{\omega}_n + m_n (\ddot{\mathbf{d}}_{0n} - \omega_n \times \mathbf{v}_n) \end{pmatrix}, \end{aligned}$$

where $\dot{\mathbf{v}}_n = \ddot{\mathbf{d}}_{0n} - \omega_n \times \mathbf{v}_n$ has been substituted. The second term on the right evaluates to

$$\begin{aligned} \mathbf{v}_n \times \mathbf{I}_n \mathbf{v}_n &= \begin{pmatrix} \mathbf{S}(\omega_n) & \mathbf{S}(\mathbf{v}_n) \\ \mathbf{0} & \mathbf{S}(\omega_n) \end{pmatrix} \\ &\quad \times \begin{pmatrix} \bar{\mathbf{I}}_n & m_n \mathbf{S}(\mathbf{c}_n) \\ m_n \mathbf{S}(\mathbf{c}_n)^T & m_n \mathbf{1} \end{pmatrix} \begin{pmatrix} \omega_n \\ \mathbf{v}_n \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{S}(\omega_n) \bar{\mathbf{I}}_n \omega_n + m_n \mathbf{S}(\mathbf{c}_n) \mathbf{S}(\omega_n) \mathbf{v}_n \\ \mathbf{S}(\omega_n) m_n \mathbf{S}(\mathbf{c}_n)^T \omega_n + \mathbf{S}(\omega_n) m_n \mathbf{v}_n \end{pmatrix}. \end{aligned}$$

Combining and simplifying,

$$\mathbf{f}_n = \begin{pmatrix} \bar{\mathbf{I}}_n \dot{\omega}_n + \mathbf{S}(\omega_n) \bar{\mathbf{I}}_n \omega_n - \mathbf{S}(\ddot{\mathbf{d}}_{0n}) m_n \mathbf{c}_n \\ m_n \ddot{\mathbf{d}}_{0n} + \mathbf{S}(\dot{\omega}_n) m_n \mathbf{c}_n + \mathbf{S}(\omega_n) \mathbf{S}(\omega_n) m_n \mathbf{c}_n \end{pmatrix}, \quad (6.40)$$

where the mass moment $m_n \mathbf{c}_n$ appears as a quantity to be estimated in combination. However, since the mass m_n is separately estimated from the $m_n \ddot{\mathbf{d}}_{0n}$ term, the center of mass \mathbf{c}_n can be extracted. To account explicitly for gravity \mathbf{g} , we substitute $\ddot{\mathbf{d}}_{0n} - \mathbf{g}$ for $\ddot{\mathbf{d}}_{0n}$ subsequently.

To formulate an estimation algorithm, the force and torque measured by the wrist sensor must be expressed in terms of the product of known geometric parameters and the unknown inertial parameters. Elements of the inertia matrix are vectorized as $\mathbf{l}(\bar{\mathbf{I}}_n)$ according to the following notation

$$\begin{aligned} \bar{\mathbf{I}}_n \omega_n &= \begin{pmatrix} \omega_1 & \omega_2 & \omega_3 & 0 & 0 & 0 \\ 0 & \omega_1 & 0 & \omega_2 & \omega_3 & 0 \\ 0 & 0 & \omega_1 & 0 & \omega_2 & \omega_3 \end{pmatrix} \begin{pmatrix} I_{11} \\ I_{12} \\ I_{13} \\ I_{22} \\ I_{23} \\ I_{33} \end{pmatrix} \\ &\equiv \mathbf{L}(\omega_n) \mathbf{l}(\bar{\mathbf{I}}_n), \end{aligned}$$

where $\mathbf{L}(\omega_n)$ is a 3×6 matrix of angular velocity elements and

$$\bar{\mathbf{I}}_n = \begin{pmatrix} I_{11} & I_{12} & I_{13} \\ I_{12} & I_{22} & I_{23} \\ I_{13} & I_{23} & I_{33} \end{pmatrix}.$$

Using these expressions, (6.40) can be written as

$$\begin{aligned} \mathbf{f}_n &= \begin{pmatrix} \mathbf{0} & -\mathbf{S}(\ddot{\mathbf{d}}_{0n}) & \mathbf{L}(\dot{\omega}_n) + \mathbf{S}(\omega_n) \mathbf{L}(\omega_n) \\ \ddot{\mathbf{d}}_{0n} & \mathbf{S}(\dot{\omega}_n) + \mathbf{S}(\omega_n) \mathbf{S}(\omega_n) & \mathbf{0} \end{pmatrix} \\ &\quad \times \begin{pmatrix} m_n \\ m_n \mathbf{c}_n \\ \mathbf{l}(\bar{\mathbf{I}}_n) \end{pmatrix} \end{aligned}$$

or more compactly,

$$\mathbf{f}_n = \mathbf{A}_n \boldsymbol{\phi}_n, \quad (6.41)$$

where \mathbf{A}_n is a 6×10 matrix, and $\boldsymbol{\phi}_n$ is the vector of the 10 unknown inertial parameters which appear linearly.

The previous formulation can be extended to all the links of a manipulator with n joints (Fig. 6.10). (Only manipulators with revolute joints will be considered, since handling prismatic joints requires only trivial modifications to the algorithm.) Define \mathbf{f}_{ij} as the spatial force at joint i due to movement of link j alone. Then \mathbf{f}_{ii} is the spatial force at joint i due to movement of its own link, and is the same as (6.41) with i substituted for n in the \mathbf{A}_n matrix

$${}^i \mathbf{f}_{ii} = {}^i \mathbf{A}_i \boldsymbol{\phi}_i, \quad (6.42)$$

where $\boldsymbol{\phi}_i$ is the vector of unknown link i inertial parameters. Superscript i has been added to indicate that vectors are expressed in terms of link i coordinates, so that the center of mass ${}^i \mathbf{c}_i$ and the inertia matrix ${}^i \bar{\mathbf{I}}_i$ are constant.

The total spatial force ${}^i \mathbf{f}_i$ at joint i is the sum of the spatial forces ${}^i \mathbf{f}_{ij}$ for all links j distal to joint i

$${}^i \mathbf{f}_i = \sum_{j=i}^n {}^i \mathbf{f}_{ij}. \quad (6.43)$$

Each spatial force ${}^i \mathbf{f}_{ij}$ at joint i is determined by transmitting the distal spatial force ${}^j \mathbf{f}_{jj}$ across intermediate joints. Using the spatial force transform matrix ${}^i \mathbf{X}_j^F$,

$${}^i \mathbf{f}_{i,i+1} = {}^i \mathbf{X}_{i+1}^F {}^{i+1} \mathbf{f}_{i+1,i+1} = {}^i \mathbf{X}_{i+1}^F {}^{i+1} \mathbf{A}_{i+1} \boldsymbol{\phi}_{i+1}. \quad (6.44)$$

For convenience, we note that ${}^i \mathbf{X}_i^F = \mathbf{1}_{6 \times 6}$. To obtain the forces and torques at the i -th joint due to the movements of the j -th link, these matrices can be cascaded

$$\begin{aligned} {}^i \mathbf{f}_{ij} &= {}^i \mathbf{X}_{i+1}^F {}^{i+1} \mathbf{X}_{i+2}^F \cdots {}^{j-1} \mathbf{X}_j^F {}^j \mathbf{f}_{jj} \\ &= {}^i \mathbf{X}_j^F {}^j \mathbf{A}_j \boldsymbol{\phi}_j. \end{aligned} \quad (6.45)$$

An upper-diagonal matrix expression for a serial kinematic chain can be derived from (6.43) and (6.45)

$$\begin{pmatrix} {}^1f_1 \\ {}^2f_2 \\ \vdots \\ {}^nf_n \end{pmatrix} = \begin{pmatrix} {}^1X_1^{F1}A_1 & {}^1X_2^{F2}A_2 & \dots & {}^1X_n^{Fn}A_n \\ \mathbf{0} & {}^2X_2^{F2}A_2 & \dots & {}^2X_n^{Fn}A_n \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \dots & {}^nX_n^{Fn}A_n \end{pmatrix} \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_n \end{pmatrix}. \quad (6.46)$$

This equation is linear in the unknown parameters, but the left-hand side is composed of a full force-torque vector at each joint. Since only the torque τ_i about the joint rotation axis z_i can usually be measured, each spatial force if_i must be projected onto the joint rotation axis, reducing (6.46) to

$$\tau = \mathbf{K}\phi, \quad (6.47)$$

where

$$\tau_i = \begin{pmatrix} z_i \\ \mathbf{0} \end{pmatrix} \cdot f_i, \quad \mathbf{K}_{ij} = \begin{pmatrix} z_i \\ \mathbf{0} \end{pmatrix} \cdot {}^iX_j^{Fj}A_j, \quad \phi = \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_n \end{pmatrix}$$

and $\mathbf{K}_{ij} = \mathbf{0}_{1 \times 10}$ if $i > j$. For an n -link manipulator, τ is an $n \times 1$ vector, ϕ is a $10n \times 1$ vector, and \mathbf{K} is an $n \times 10n$ matrix.

For geared electric drives, joint torque may either be measured by joint torque sensors (Chap. 28) or estimated from the motor current by using an electric motor model (Chap. 8). Most robots do not have joint torque sensors, in which case joint friction needs to be taken into account. Joint friction typically consumes a large fraction of the torque that the motor produces. Coulomb and viscous friction are the most important components of a friction model, although Stribeck friction may need to be modeled for low joint velocities [6.24, 25]. A friction model is estimated through a process of moving one joint at a time, and relating motor torque to velocity. Ripple torque, due either to uncompensated inhomogeneities of the magnetic field in the motor [6.26, 27], or to positional dependencies of gear tooth interaction [6.24], may need to be modeled.

Equation 6.47 represents the dynamics of the manipulator for one sample point. It can be rewritten

using P data points as with geometric calibration

$$\tau = \mathbf{K}\phi, \quad \mathbf{K} = \begin{pmatrix} \mathbf{K}^1 \\ \vdots \\ \mathbf{K}^P \end{pmatrix}, \quad \tau = \begin{pmatrix} \tau^1 \\ \vdots \\ \tau^P \end{pmatrix}, \quad (6.48)$$

where τ is now an $nP \times 1$ vector and \mathbf{K} is now $nP \times 10n$.

Unfortunately, one cannot apply simple least-squares estimation because $\mathbf{K}^T\mathbf{K}$ is not invertible due to the loss of rank from restricted degrees of freedom at the proximal links and the lack of full force-torque sensing. Some inertial parameters are completely unidentifiable, while some others can only be identified in linear combinations. The general topic of identifiability of parameters, and how to handle unidentifiable parameters, is discussed next.

An issue with geared electric drives is the rotor inertia. If not known, the rotor inertia can be added to the list of 10 inertial parameters to be identified for a link [6.28]. For large gear ratios, the rotor inertia can dominate the other components of link inertia.

6.3.2 Load Inertial Parameter Estimation

The load is considered as a rigid body held by the end effector. It has 10 inertial parameters: mass m_L , first moments $m_L c_L$ relative to O_n and symmetric inertia matrix $\bar{\mathbf{I}}_L$ referred here to origin O_n (Fig. 6.11). The estimation of these parameters can be used to tune the control law parameters in order to improve the dynamic accuracy of the robot, or to compensate for its dynamics by the control. They can also be exploited to verify the load transported by the robot. Two procedures are presented to estimate the load inertia parameters: the first one assumes that there is a wrist-mounted 6-axis force/torque sensor, whereas the second one makes use of the joint torques.

Fig. 6.11 Dynamics of the last link

Using 6-Axis Forces/Torque Sensor

Kinematically, the force-torque sensor is part of the last link n , mounted near the joint axis z_n and origin O_n . The sensor provides readings relative to its own coordinate system, called $n+1$ (Fig. 6.11). The remainder of the last link is attached to the shaft of the force-torque sensor, and so the force-torque sensor is measuring the loads on the last link excluding itself. The acceleration of the force-torque sensor reference frame would have to be calculated based on the amount of offset from O_n , but we will ignore that complication here and assume that the sensor origin O_{n+1} is coincident with O_n .

The estimation of load inertial parameters can be carried out using (6.41).

The quantities inside the A_n matrix are computed by direct kinematics computation from the measured joint angles, and from the estimated joint velocities and accelerations. The estimation is typically done by bandpass filtering of the joint angle data [6.29]. The elements of the f_n vector are measured directly by the wrist force sensor. For robust estimates in the presence of noise, a larger number of P data points are obtained by moving the manipulator through a suitable trajectory. Augment f_n and A_n as

$$A = \begin{pmatrix} A_n^1 \\ \vdots \\ A_n^P \end{pmatrix}, \quad f = \begin{pmatrix} f_n^1 \\ \vdots \\ f_n^P \end{pmatrix}, \quad (6.49)$$

where P is the number of data points. The least-squares estimate for ϕ_L is given by

$$\hat{\phi}_L = (A^T A)^{-1} A^T f. \quad (6.50)$$

For object recognition, it may be desired to derive the inertia about the center of mass, which can be done with the parallel axis theorem. An eigenvalue analysis can diagonalize the inertia matrix to reveal the principal axes and inertia.

Using Joint Torques

When the robot is holding a payload, the dynamic identification (6.48) can be rewritten as follows

$$\tau = K\phi + K_L\phi_L, \quad (6.51)$$

where τ contains the measured joint torques when the robot is holding a load for P points. Using (6.51) in the identification will result in grouping ϕ_L with ϕ_n and with other link parameters. The load parameters can be deduced by examining how the load parameters have modified the values of the grouped inertial parameters using the expressions of grouping relations [6.30]. In the following we present three methods to identify ϕ_L parameters without using the grouping expressions.

Using a Priori Link Parameters Estimates. In this case we suppose that the robot parameters without load have been estimated as given in Sec. 6.3.1. By substituting the robot parameters into (6.51) the 10 inertial parameters of the load are identifiable and can be estimated using the least squares solution of [6.31]

$$(\tau - K\phi) = K_L\phi_L. \quad (6.52)$$

In this method we suppose that the friction parameters are invariant with respect to the payload. If this hypothesis is not true the friction parameters must be re-estimated at the same step with ϕ_L .

Using Joint Torques on the Same Trajectory Twice with and Without the Load. Since the vector $K\phi$ of (6.52) is equal to the joint torques without load, consequently, the payload inertial parameters could be identified by (6.52) after replacing $K\phi$ by τ_0 representing the joint torques on the same trajectory without load

$$(\tau - \tau_0) = K_L\phi_L. \quad (6.53)$$

This method assumes that the difference between the joint variables with and without payload is negligible and that the friction parameters are the same with and without load. If the friction parameters vary with respect to the load we can estimate this variation at the same time as the load inertial parameter.

Estimating the Robot Parameters and the Load Parameters in One Step. In this method the identification model is constructed by grouping two sets of equations: the first using a trajectory without load, and the second using a trajectory when the robot is holding the load. In this case the two sets of trajectories could be different. The link parameters and the payload inertial parameters are estimated using the least squares solution of

$$\begin{pmatrix} \tau_a \\ \tau_b \end{pmatrix} = \begin{pmatrix} K_a & \mathbf{0} \\ K_b & K_L \end{pmatrix} \begin{pmatrix} \phi \\ \phi_L \end{pmatrix}, \quad (6.54)$$

where the indices a and b indicate the trajectories without and with load, respectively.

This method has the advantage of using a global identification procedure that can avoid the accumulation of errors of previous methods.

These three methods have been validated experimentally on the 6-DOF robot RX-90 of Staubli. They give similar results [6.30].

6.3.3 Identification of Total Joint Drive Gains

For gear electric drive of joint j , the joint torque τ_j is estimated as $\tau_j = v_{rj}g_j$, where v_{rj} is the control signal computed by the numerical controller of the robot (the input references of the motor current loop) and g_j is the total joint j drive gain, given by the gear ratio, the current amplifier gain, and the motor torque constant.

Because of large values of the gear ratio for industrial robots, (> 50), joint drive gain is very sensitive to errors and must be accurately measured from special, time consuming, heavy tests, on the drive chain [6.32, 33].

The methods used to identify the load inertial parameters using joint torques can be inverted to identify the drive gains. In this case some load inertial parameters ϕ_{kL} must be known while the other unknown parameters ϕ_{uL} are identified with the gain g .

The vector τ of sampled joint torques in (6.52) or (6.54) is rewritten as

$$\tau = \mathbf{V}_r \mathbf{g}, \quad (6.55)$$

where: \mathbf{g} is the $(n \times 1)$ vector of the joint drive gains, \mathbf{V}_r regroups the samples of v_{rj} .

Using the Same Set of Trajectory Twice, with and Without the Load

Introducing (6.55) and the known load inertial parameters in (6.53) with the expression

$$\mathbf{K}_L \phi_L = \mathbf{K}_{kL} \phi_{kL} + \mathbf{K}_{uL} \phi_{uL} \quad (6.56)$$

gives

$$(\mathbf{V}_r - \mathbf{V}_{ruL})\mathbf{g} = \mathbf{K}_{kL} \phi_{kL} + \mathbf{K}_{uL} \phi_{uL}. \quad (6.57)$$

This equation can be used to identify ϕ_{uL} and \mathbf{g} as the *LS* solution of the system

$$[\mathbf{K}_{kL} \phi_{kL}] = ((\mathbf{V}_r - \mathbf{V}_{ruL}) \quad -\mathbf{K}_{uL}) (\mathbf{g}^T \quad \phi_{uL}^T)^T. \quad (6.58)$$

Using Two Sets of Trajectories (Same or Different), the First Set Without Load and the Second Set with the Load

Introducing (6.55) and the known load inertial parameters (6.56) in (6.54) gives

$$\begin{pmatrix} \mathbf{V}_{ra} \\ \mathbf{V}_{rb} \end{pmatrix} \mathbf{g} = \begin{pmatrix} \mathbf{K}_a & 0 & 0 \\ \mathbf{K}_b & \mathbf{K}_{uL} & \mathbf{K}_{kL} \end{pmatrix} (\phi^T \quad \phi_{uL}^T \quad \phi_{kL}^T)^T. \quad (6.59)$$

Equation (6.59) can be used to identify all the parameters, \mathbf{g} , ϕ and ϕ_{uL} , as the single global *LS* solution

of the system

$$\begin{pmatrix} 0 \\ \mathbf{K}_{kL} \phi_{kL} \end{pmatrix} = \begin{pmatrix} \mathbf{V}_{ra} & -\mathbf{K}_a & 0 \\ \mathbf{V}_{rb} & -\mathbf{K}_b & -\mathbf{K}_{uL} \end{pmatrix} (\mathbf{g}^T \quad \phi^T \quad \phi_{uL}^T)^T. \quad (6.60)$$

But owing to the fact that \mathbf{K}_{kL} and \mathbf{K}_{uL} are correlated by the same noisy data (q, \dot{q}, \ddot{q}) , the total least squares (TLS) solution is used to avoid bias errors of the ordinary *LS* solution [6.34]. Rewriting (6.60) as

$$\mathbf{K}_{\text{tot}} \phi_{\text{tot}} = \mathbf{0}, \quad (6.61)$$

where

$$\mathbf{K}_{\text{tot}} = \begin{pmatrix} \mathbf{V}_{ra} & -\mathbf{K}_a & 0 & 0 \\ \mathbf{V}_{rb} & -\mathbf{K}_b & -\mathbf{K}_{uL} & -\mathbf{K}_{kL} \phi_{kL} \end{pmatrix}, \quad (6.62)$$

$$\phi_{\text{tot}} = (\mathbf{g}^T \quad \phi^T \quad \phi_{uL}^T \quad 1)^T. \quad (6.63)$$

The singular value decomposition (SVD) of \mathbf{K}_{tot} is given by

$$\mathbf{K}_{\text{tot}} = \mathbf{U} \mathbf{S} \mathbf{V}^T, \quad (6.64)$$

where \mathbf{U} and \mathbf{V} are orthonormal matrices, and $\mathbf{S} = \text{diag}(s_i)$ is a diagonal matrix with singular values s_i of \mathbf{K}_{tot} sorted in decreasing order. There are infinity of vectors $\hat{\phi}_{\text{tot}} = \lambda \mathbf{V}_c$ which are the *TLS* solutions of (6.61), depending on a scale factor λ and on the normalized *TLS* solution given by the last column \mathbf{V}_c of \mathbf{V} , $\|\mathbf{V}_c\| = 1$, corresponding to the smallest singular value s_c [6.34]. The unique solution $\hat{\phi}_{\text{tot}}^*$ assumes that its last coefficient $\hat{\phi}_{\text{tot}}^*(\text{end})$ must be equal to 1 according to (6.63) such as

$$\hat{\phi}_{\text{tot}}^* = \frac{\mathbf{V}_c}{\mathbf{V}_c(\text{end})} \quad (6.65)$$

The methods has been successfully experimentally validated on the 6-DOF Staubli TX-40 industrial robot [6.35].

This approach is very simple to perform and the experimental results have shown its effectiveness: for the global identification of the total joint drive gains and the dynamic parameters, it is only necessary to accurately weigh a payload mass and to carry standard trajectories of industrial robot.

6.3.4 Link Parameter Estimation for More Complex Structures

In this section we present the dynamic identification model for kinematic tree (spanning tree) robots and

kinematic closed-loop robots including parallel robots. These models are linear in the inertial parameters and can be represented by a model similar to (6.47), thus these parameters can be identified using the same techniques.

Tree-Structured Robots

For an n -link manipulator with a kinematic tree structure, the dynamic identification model (6.46) must be modified to take into account that the inertial parameters of link j have no effect on the dynamics of links which do not belong to the chain from the base to that link. For such structures, the link on which link j is articulated is denoted by $p(j)$ (parent of j – see Sect. 3.4). It could be a link with any number i , such that $i < j$. Thus the nonzero elements of the column of the matrix representing the coefficients of the inertial parameters of link j in (6.46) would be

$$j\mathbf{X}_j^{\text{Fj}}\mathbf{A}_j, p(j)\mathbf{X}_j^{\text{Fj}}\mathbf{A}_j, p(p(j))\mathbf{X}_j^{\text{Fj}}\mathbf{A}_j, \dots, b\mathbf{X}_j^{\text{Fj}}\mathbf{A}_j, \quad (6.66)$$

where b is the first link of the chain connecting link 0 to link j , thus $p(b) = 0$.

Consequently, in (6.47) of a tree robot we obtain: $\mathbf{K}_{ij} = \mathbf{0}_{1 \times 10}$ if $i > j$ or if link i does not belong to the branch connecting link 0 to link j . This means that some elements of the upper-right submatrix of \mathbf{K} will be zero.

We note that a serial structure is a particular case of a tree structure where $p(j) = j - 1$. Thus any link m such that $m < j$ will belong to the chain from the base to link j .

Closed-Loop Robots

The dynamic model of a closed-loop structure can be obtained by considering first an equivalent spanning tree by opening one joint at each closed loop, and then using the principle of virtual work such that

$$\boldsymbol{\tau} = \mathbf{G}^T \mathbf{K}_{\text{tr}} \boldsymbol{\phi}, \quad \mathbf{G} = \left(\frac{\partial \mathbf{q}_{\text{tr}}}{\partial \mathbf{q}_a} \right), \quad (6.67)$$

with \mathbf{q}_a an $N \times 1$ vector of N active joint angles (N differs from n , the total number of joints), and \mathbf{q}_{tr} an $n \times 1$ vector of the joints of the spanning tree structure.

Parallel Robots

A parallel robot is a particular case of closed-loop robots (Chap. 18). It is composed of a moving platform, representing the terminal link, that is connected to the base by m parallel legs. The dynamic model of parallel robots can be given by [6.36]

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{A}_p \boldsymbol{\phi}_p + \sum_{i=1}^m \left(\frac{\partial \mathbf{q}_i}{\partial \mathbf{q}_a} \right)^T \mathbf{K}_i \boldsymbol{\phi}_i, \quad (6.68)$$

where $\mathbf{K}_i \boldsymbol{\phi}_i$ represents the dynamic model of leg i with \mathbf{K}_i a function of $(\mathbf{q}_i, \dot{\mathbf{q}}_i, \ddot{\mathbf{q}}_i)$, \mathbf{q}_i is the vector of joint angles of leg i , $\mathbf{A}_p \boldsymbol{\phi}_p$ is the Newton–Euler spatial force of the platform calculated in terms of the Cartesian variables of the mobile platform using (6.41), and \mathbf{J} is the Jacobian matrix of the parallel manipulator. We can obtain (6.68) from (6.67) by supposing that the spanning tree structure is obtained by separating the mobile platform from the legs.

Equation 6.68 can be rewritten as

$$\begin{aligned} \boldsymbol{\tau} &= [\mathbf{J}^T \mathbf{A}_p \quad (\partial \mathbf{q}_1 / \partial \mathbf{q}_a)^T \mathbf{K}_1 \quad \dots \quad (\partial \mathbf{q}_m / \partial \mathbf{q}_a)^T \mathbf{K}_m] \\ &\quad \boldsymbol{\phi}_{\text{par}} \\ \boldsymbol{\tau} &= \mathbf{K}_{\text{par}} (\boldsymbol{\omega}_p, \dot{\boldsymbol{\omega}}_p, \dot{\mathbf{q}}_p, \mathbf{q}_i, \dot{\mathbf{q}}_i, \ddot{\mathbf{q}}_i) \boldsymbol{\phi}_{\text{par}}, \end{aligned} \quad (6.69)$$

where $\boldsymbol{\phi}_{\text{par}}$ is the vector of the inertial parameters of the robot (the legs and the platform).

$$\boldsymbol{\phi}_{\text{par}} = \begin{pmatrix} \phi_p \\ \phi_1 \\ \vdots \\ \phi_m \end{pmatrix}.$$

In the common case where the legs are identical and their inertial parameters are denoted by $\boldsymbol{\phi}_{\text{leg}}$, the identification model can be rewritten by the following equation, which considerably reduces the number of inertial parameters to be identified

$$\boldsymbol{\tau} = [\mathbf{J}^T \mathbf{A}_p \quad \sum_{i=1}^m (\partial \mathbf{q}_i / \partial \mathbf{q}_a)^T \mathbf{K}_i] \begin{pmatrix} \phi_p \\ \boldsymbol{\phi}_{\text{leg}} \end{pmatrix}. \quad (6.70)$$

The identification of the orthoglide parallel robot is given in [6.37].

6.4 Identifiability and Numerical Conditioning

That some inertial parameters in (6.47) are unidentifiable does not mean that they are intrinsically identifiable, only that the experimental setup does not allow them to be identified. Limited motion near the base could be fixed by placing the whole manipulator on

a six-axis moving platform such as a Stewart–Gough platform. In fact, for mobile manipulators mounted on high-mobility vehicles such as satellites, it may be necessary to know the full inertial model of the manipulator. Additional sensors could be added, for ex-

ample a six-axis force-torque sensor to the base of the robot [6.5], to identify some additional (but not all) inertial parameters.

A similar situation may arise in kinematic calibration, where for example joint models might be augmented to include gear eccentricities, transmission and coupling coefficients of gears, joint elasticity, link elasticity, and base deflection [6.38]. By instrumenting the robot with additional sensors, for example, by placing joint angle sensors before and after the gears to measure joint deflection, it may be possible to identify additional parameters of interest. Additional sensing with a theodolite was done to measure base deflection in [6.12].

Given that the experimental setup is what it is, there may be no recourse but to deal with unidentifiable parameters, treated in the next section. Another problem is that parameters might in principle be identifiable, but numerical conditioning prevents their accurate determination. Issues such as adequacy of the collected data, and the effect of different units and magnitudes of parameters, are treated subsequently.

6.4.1 Identifiability

There are two main approaches towards handling unidentifiable parameters, depending on whether the goal is a structural model or a prediction model. For a structural model, the goal is to find the minimum parameter set that provides a meaningful physical description of the system by eliminating parameters until all are identifiable. This is done by careful evaluation of the effect of each parameter of the original model.

For a prediction model, the goal is to match the outputs to the inputs as closely as possible, and is more of a curve-fitting approach. The resulting parameter values are not necessarily physically meaningful or accurate.

Structural Model

It may be possible in the initial model formation to avoid including redundant or unidentifiable parameters. At other times, it is not possible to determine a priori what the minimal parameter set is, because of system complexity or because of numerical difficulties such as measurement error or limitations in the collected data.

A Priori Parameter Elimination. In the initial model formation, the choice of representation can immediately dictate whether the model is redundant or minimal. For kinematic calibration, the minimal parameter set includes four parameters for a rotary joint and two parameters for a prismatic joint. The detailed presentation in Sect. 6.2.1 of how to set up the DH/Hayati parameters for different kinematic and sensing arrangements

has the advantage that the parameter set is minimal (excepting joint models). Once done, the application to any manipulator is somewhat formulaic.

Five- and six-parameter joint models have also been proposed, either for the convenience of locating link coordinate systems or for the ease of model formation [6.13, 28, 39]. With such redundant parameter sets, extra steps must be taken to handle the numerical difficulties caused by the redundancy, such as by reducing the number of parameters in a postprocessing step. When there are complicated joint models that include gearing effects as mentioned above, the resultant large numbers of parameters make the parameter elimination problem more difficult. Determining the minimal set of inertial parameters offers a different sort of complexity, because large numbers of parameters are not identifiable or are identifiable only in linear combinations. Again, model reduction is one approach to handle this problem.

Two approaches towards determining a minimal or base parameter set are:

1. Numerical identification of the unidentifiable parameters or linear combinations of parameters.
2. Symbolic determination.

Numerical identification involves rank reduction through matrix manipulation of the regressor, either through QR decomposition or singular value decomposition [6.40]. If the kinematic or dynamic model is known exactly, then a simulation using exactly generated data will yield a noise-free regressor matrix \mathbf{A} in (6.3). For QR decomposition, the regressor matrix is factored as

$$\mathbf{A} = \mathbf{Q} \begin{pmatrix} \mathbf{R} \\ \mathbf{0}_{MP-N_{\text{par}}, N_{\text{par}}} \end{pmatrix}, \quad (6.71)$$

where \mathbf{Q} is an $M \times MP$ orthogonal matrix, \mathbf{R} is an $N_{\text{par}} \times N_{\text{par}}$ upper-triangular matrix, and $\mathbf{0}_{MP-N_{\text{par}}, N_{\text{par}}}$ is the zero matrix with dimensions $MP - N_{\text{par}} \times N_{\text{par}}$. Theoretically, the unidentifiable parameters ϕ_i are those whose corresponding diagonal elements R_{ii} of matrix \mathbf{R} are zero. In practice, $|R_{ii}|$ is considered to be zero if it is less than the numerical zero ζ [6.41]

$$\zeta = MP\epsilon \max_i |R_{ii}|, \quad (6.72)$$

where ϵ is the computer precision [6.41]. Other parameters may appear in linear combinations depending on how many nonzero elements there are in row j of \mathbf{R} . Resolving these linear combinations is arbitrary. One approach is to zero all elements in the linear combination save one. The result is a prediction model rather than a structural model.

Symbolic determination of the base inertial parameters has been proposed in [6.40, 42]. Using an energy formulation, the total energy of link j is expressed as $\mathbf{h}_j \phi_j$, where \mathbf{h}_j is a row vector termed the total energy function whose elements are kinematic expressions of the angular and linear velocity of link j plus gravity. A recursive relation between neighboring links is developed as

$$\mathbf{h}_j = \mathbf{h}_{j-1}^{j-1} \lambda_j + \dot{q}_j \boldsymbol{\eta}_j, \quad (6.73)$$

where the elements of the 10×10 matrix $^{j-1} \lambda_j$ are functions of the DH parameters defining frame j , and the elements of the 1×10 row vector $\boldsymbol{\eta}_j$ depend on the linear and angular velocities. The details of these expressions can be found in [6.40, 42]. Grouping rules are then developed to find the precise linear combinations of parameters.

The minimum inertial parameters for a tree structure can be obtained using a closed-form solution similar to the serial structure case [6.42].

The term $\mathbf{K}_{tr} \phi$ in (6.67) shows that the minimum parameters of the spanning tree structure can be used to calculate the dynamics of the closed structure, giving by this a first reduction and grouping of the inertial parameters. However extra parameters can be eliminated or grouped when considering the matrix \mathbf{G} . The case of parallelogram loops can be treated symbolically using closed-form relations [6.42]. For general closed loops, the minimum parameters must be determined using numerical methods such as QR decomposition [6.40].

In the case of parallel robots, we deduce from (6.68) that the minimum parameters of the legs can be used to calculate $\mathbf{K}_i \phi_i$, giving a first reduction of the inertial parameters. However, some other parameters can be grouped with the parameters of the platform. The minimum parameters of the Gough–Stewart robot are given in [6.43].

Data-Driven Parameter Elimination. The singular value decomposition of the regressor matrix can show which parameters are unidentifiable, weakly identifiable, or identifiable only in linear combination. For N_{par} parameters, P data points, and M -dimensional output measurements at each data point, the regressor matrix \mathbf{A} (6.3) or (6.7) can be decomposed as

$$\mathbf{A} = \mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^T, \quad (6.74)$$

where \mathbf{U} is an $MP \times MP$ orthogonal matrix, \mathbf{V} is an $N_{\text{par}} \times N_{\text{par}}$ orthogonal matrix, and $\boldsymbol{\Sigma}$ is the $MP \times N_{\text{par}}$ matrix of singular values

$$\boldsymbol{\Sigma} = \begin{pmatrix} \mathbf{S} \\ \mathbf{0}_{MP-N_{\text{par}}, N_{\text{par}}} \end{pmatrix}, \quad (6.75)$$

where $\mathbf{S} = \text{diag}(\mu_1, \dots, \mu_r, 0, \dots, 0)$ is the $N_{\text{par}} \times N_{\text{par}}$ matrix of ordered singular values, with μ_1 the largest and μ_r the smallest nonzero singular value. There may be $N_{\text{par}} - r$ zero singular values $\mu_{r+1} = \dots = \mu_{N_{\text{par}}} = 0$.

Especially when complex joint models are assumed that include flexibility, backlash, and gear eccentricity, it is not clear that all parameters can be identified. Retaining poorly identifiable parameters will degrade the robustness of the calibration; such parameters are indicated by zero or very small singular values. The expansion of (6.7) in terms of (6.74) is

$$\Delta \mathbf{y} = \sum_{j=1}^r \mu_j (\mathbf{v}_j^T \Delta \boldsymbol{\phi}) \mathbf{u}_j, \quad (6.76)$$

where \mathbf{u}_j and \mathbf{v}_j are the j -th columns of \mathbf{U} and \mathbf{V} . For zero or small singular values μ_j , the projection $\mathbf{v}_j^T \Delta \boldsymbol{\phi}$ of the parameters onto the column vector \mathbf{v}_j in general represents a linear combination of parameters. It is also possible that only a single parameter results from the projection.

To proceed, it is first necessary to scale the parameters and the output measurements so that the singular values are comparable. Scaling is discussed in Sect. 6.4.3. Small singular values signal that there are parameters that are poorly identifiable and that should be eliminated. By small singular values, Schröer [6.38] suggests the heuristic that the *condition number* of a well-conditioned regressor matrix should be less than 100

$$\kappa(\mathbf{A}) = \frac{\mu_1}{\mu_r} < 100. \quad (6.77)$$

This heuristic derives from experience of their statistical community. If the condition number is above 100, the singular values are examined, beginning with the smallest one, which may be a zero singular value.

If the condition number is above 100, the linear sums (6.76) corresponding to the smallest singular value μ_r are examined. The elements of column \mathbf{v}_r are in one-to-one correspondence with the elements of $\Delta \boldsymbol{\phi}$. If there is an element j of \mathbf{v}_r that is much larger than the others, then the parameter ϕ_j corresponding to that column element is a candidate for elimination. This procedure will tend to pinpoint parameters that are totally unidentifiable. Isolating the largest element of \mathbf{v}_r is once again only meaningful if the parameters have been previously scaled.

Once the parameter is eliminated, the condition number of the reduced regressor is computed again. The procedure iterates until the condition number of the regressor is below 100.

The previous procedure can be carried out using QR decomposition as in (6.71), by replacing ϵ representing

the computer precision in (6.72) by a greater value function of the noise level.

Prediction Model

If there are several largest elements of \mathbf{v}_r that are roughly comparable in magnitude, then these parameters may only be identifiable in linear combination. There will be the same number of singular values which are too small. By examining several columns \mathbf{v}_j corresponding to the small singular values, these linear combinations can become apparent. The linear combinations can be resolved arbitrarily, i.e., all parameter elements in the linear combination save one can be set to zero. The result of zeroing some parameters is that the model is no longer a structural model, but rather a prediction model.

One may also proceed without first removing parameters. It can be shown by substituting the singular value decomposition that

$$(\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T = \mathbf{V} (\mathbf{S}^{-1} \mathbf{0}_{N_{\text{par}}, MP-N_{\text{par}}}) \mathbf{U}^T. \quad (6.78)$$

Consequently the solution to (6.8) can be expressed as [6.44]

$$\Delta \phi = \sum_{j=1}^{N_{\text{par}}} \frac{\mathbf{u}_j^T \Delta \mathbf{y}}{\mu_j} \mathbf{v}_j. \quad (6.79)$$

One can see that poorly identifiable parameters corresponding to small singular values μ_j greatly perturb the estimates, because the weighting is $1/\mu_j$. The strategy is to remove their influence. If μ_j is zero or very small relative to the largest singular value μ_1 , then set $1/\mu_j = 0$.

Parameters that cannot be identified well are simply ignored in this procedure, which automatically converges to an identifiable parameter set. The resulting parameters can then be used for the model. A disadvantage is that the resulting parameters may not correspond to real model parameters. A procedure to project these parameters on the real ones is given in [6.40].

Incorporating A Priori Parameter Estimates

Least squares treats parameter values as completely unknown, i.e., they could be anywhere in the range from $-\infty$ to $+\infty$. Yet often a fairly good initial estimate of the parameters is available, for example, from a manufacturer's specifications or in the case of a recalibration. It makes sense to incorporate such an a priori preference into the least-squares optimization [6.45].

Suppose there is a preference for a solution near $\phi = \phi_0$. Express the preference as $\mathbf{I}\phi = \phi_0$, where \mathbf{I} is the identity matrix, and append it as addi-

tional rows to (6.3) that reflect this preference

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{I} \end{pmatrix} \phi = \begin{pmatrix} \mathbf{y} \\ \phi_0 \end{pmatrix}. \quad (6.80)$$

To proceed with the solution, we can treat ϕ_0 as a constant. Redefine the parameter vector as $\tilde{\phi} = \phi - \phi_0$, which we expect to be close to zero. Then

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{I} \end{pmatrix} \tilde{\phi} = \begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{0} \end{pmatrix}, \quad (6.81)$$

where $\tilde{\mathbf{y}} = \mathbf{y} - \mathbf{A}\phi_0$. We may not know ϕ_0 perfectly well, so we add a weighting parameter λ to express the confidence in this value

$$\begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{I} \end{pmatrix} \tilde{\phi} = \begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{0} \end{pmatrix}. \quad (6.82)$$

The larger is λ , the more confidence we have in our a priori estimate. The least-squares solution is therefore

$$\begin{aligned} \tilde{\phi} &= \left(\begin{pmatrix} \mathbf{A}^T & \lambda \mathbf{I} \end{pmatrix} \begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{I} \end{pmatrix} \right)^{-1} \begin{pmatrix} \mathbf{A}^T & \lambda \mathbf{I} \end{pmatrix}^T \begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{0} \end{pmatrix} \\ &= (\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{I})^{-1} \mathbf{A}^T \tilde{\mathbf{y}}. \end{aligned} \quad (6.83)$$

This solution is called *damped least squares*, where λ is the damping factor. Expanding this solution in terms of the singular value decomposition,

$$\tilde{\phi} = \sum_{j=1}^{N_{\text{par}}} (\mathbf{u}_j^T \tilde{\mathbf{y}}) \frac{\mu_j}{\mu_j^2 + \lambda^2} \mathbf{v}_j. \quad (6.84)$$

Hence a very small μ_j is counteracted by the larger λ value; then the a priori information about parameter values dominates the information from the data, i.e., the data are ignored. Thus for damped least squares, no explicit action on the singular values is required, because the damping factor modifies the singular values. The solution will be perturbed over the normal least-squares solution by the magnitude of the λ choice.

Confidence Measure of Parameter Estimates

After calibration, an estimate $\hat{\mathbf{M}}$ of the covariance of the parameter estimates can be derived from the data [6.3]. Assume that the task variables $\Delta \mathbf{y}$ have previously been scaled for equal uncertainty, that there is no bias, and that the errors are uncorrelated. Then

$$\hat{\mathbf{M}} = \sigma^2 (\mathbf{A}^T \mathbf{A})^{-1}. \quad (6.85)$$

An estimate of the standard deviation σ after running the calibration procedure is obtained from the χ^2 statistic [6.44, 46]

$$\chi^2 = (\Delta \mathbf{y} - \mathbf{A} \Delta \hat{\phi})^T (\Delta \mathbf{y} - \mathbf{A} \Delta \hat{\phi}). \quad (6.86)$$

An unbiased estimator for σ^2 is $\hat{\sigma}^2 = \chi^2/\nu$, where $\nu = MP - N_{\text{par}}$ is called the statistical *degrees of freedom*; ν subtracts from the total number of measurements MP the number N_{par} of parameters estimated, since some of the measurements went into determining $\hat{\phi}$.

The estimate $\hat{\mathbf{M}}$ can be used as a basis for eliminating parameters, by choosing those with the largest variances.

6.4.2 Observability

The measurements that are taken will influence the accuracy of parameter estimation. In kinematic calibration, the quality of the pose set has been measured by an *observability index*. In inertial parameter estimation, the quality of the identification trajectory has been termed *persistent excitation* [6.47]. Regardless of whether data is collected statically as in kinematic calibration or dynamically as in inertial parameter estimation, the result is just a bunch of numbers that go into the regressor matrix, and so common terminology is appropriate.

In statistics, optimal experimental design theory has given rise to several data measures termed *alphabet optimalities* [6.48]. Some of the most prominent are the following:

- *A-optimality* minimizes the trace of $(\mathbf{A}^T \mathbf{A})^{-1}$ to obtain regression designs.
- *D-optimality* maximizes the determinant of $(\mathbf{A}^T \mathbf{A})^{-1}$.
- *E-optimality* maximizes the minimum singular value of $(\mathbf{A}^T \mathbf{A})^{-1}$.
- *G-optimality* minimizes the maximum prediction variance, and does not have a simple expression in terms of singular values.

Although ties to the experimental design literature have not typically been made [6.49], several of the proposed observability indexes for robot calibration have an alphabet-optimality counterpart. A-optimality does not have a counterpart in the robot calibration literature, and conversely a few proposed observability indexes do not have an alphabet-optimality counterpart. In [6.49], it is proved that E-optimality and G-optimality are equivalent for exact design.

Borm et al. [6.50, 51] proposed an observability index (here termed O_1 and numbered consecutively below) that maximizes the product of all of the singular values

$$O_1 = \frac{\sqrt{\mu_1 \cdots \mu_r}}{\sqrt{P}}. \quad (6.87)$$

This is similar to D-optimality. The rationale is that O_1 represents the volume of a hyperellipsoid in $\Delta \mathbf{y}$, defined by (6.7) when $\Delta \phi$ defines a hypersphere, and the singular values represent the lengths of axes. Therefore maximizing O_1 gives the largest hyperellipsoid volume, and hence a good aggregate increase of the singular values. One can also derive O_1 from the well-known relation $\sqrt{\det(\mathbf{A}^T \mathbf{A})} = \mu_1 \cdots \mu_r$.

Minimizing the condition number of \mathbf{A} as a measure of observability has been proposed in [6.40, 52, 53]

$$O_2 = \frac{\mu_1}{\mu_r}. \quad (6.88)$$

O_2 measures the eccentricity of the hyperellipsoid rather than its size. The intermediate singular values are not considered to be that pertinent, because minimizing the condition number automatically makes all singular values become more similar in magnitude and makes the hyperellipsoid closer to a hypersphere.

Nahvi et al. [6.22] argue for maximizing the minimum singular value μ_r as an observability measure

$$O_3 = \mu_r. \quad (6.89)$$

This is similar to E-optimality. The rationale is to make the shortest axis as long as possible, regardless of the other axes, that is to say, to improve the worst case. Consider the following standard result [6.4]

$$\mu_r \leq \frac{\|\Delta \mathbf{y}\|}{\|\Delta \phi\|} \leq \mu_1, \quad (6.90)$$

or more particularly

$$\mu_r \|\Delta \phi\| \leq \|\Delta \mathbf{y}\|. \quad (6.91)$$

Then maximizing μ_r ensures that a given size of parameter errors $\|\Delta \phi\|$ has the largest possible influence on the pose errors $\|\Delta \mathbf{y}\|$.

Nahvi and Hollerbach [6.54] proposed the noise amplification index O_4 , which can be viewed as combining the condition number O_2 with the minimum singular value O_3

$$O_4 = \frac{\sigma_r^2}{\sigma_1}. \quad (6.92)$$

The rationale is to measure both the eccentricity of the ellipse through O_2 as well as the size of the ellipse through O_3 . The noise amplification index was argued to be the most sensitive to measurement error and modeling error.

Hollerbach and Lokhorst [6.21] found experimentally that the condition number and the minimum singular value gave about the same good result: their

relative magnitudes were almost proportional to the root-mean-square (RMS) errors of the final parameter errors. The observability index O_1 was not as sensitive and not directly related to parameter errors. *Sun* and *Hollerbach* [6.49] derived general relations among the observability indexes and alphabet optimalities

$$O_1 \geq \text{A-optimality} \geq O_3. \quad (6.93)$$

They further showed that if $\mu_1 \geq 1$, then $O_3 \geq O_2$, and if $\mu_r \leq 1$, then $O_2 \geq O_4$. They also argued that O_3 (D-optimality) is in general the best index, because it minimizes the variance of the parameters and also minimizes the uncertainty of the end-effector pose.

Optimal Experimental Design

An observability index is typically used to decide how many data points to collect. As one begins to add data points, the observability increases, then plateaus. Adding additional data does not then improve the quality of the estimates. For kinematic calibration, data may be added through random selection, or optimal design methods can be employed that can drastically reduce the amount of data required [6.55, 56]. Optimal experimental designs work by measuring the effect of adding or exchanging data points [6.57].

Exciting Trajectories

For inertial parameter estimation, data points are not independent because they result from a trajectory rather than isolated poses. Therefore the issue is what type of trajectory to generate. Industrial robots usually have joint position point-to-point trajectory generators. A continuous and smooth trajectory is calculated by interpolating between these points, assuming zero initial and final velocity and acceleration at each point, and using polynomial interpolators. Excitation trajectories are obtained by minimizing an observability index, using nonlinear optimization techniques to calculate the polynomial coefficients, under the constraints of the joint positions, velocities, and accelerations limits [6.52].

It is possible to facilitate the optimization by proceeding to a sequential excitation procedure. Specific trajectories, which structurally excite a small number of parameters, are easier to optimize. For example, moving one joint at a time with constant velocities excites friction and gravity parameters. In this approach, sequential identification is avoided. However, it is better to collect all the data and to proceed to a globally weighted least-squares estimation [6.29]. This procedure avoids the accumulation of estimation errors and allows the calculation of the confidence intervals (6.85).

Specific trajectories have been proposed like sinusoidal interpolators [6.58], or periodic trajec-

tries obtained from a spectral analysis of the contribution function of the parameters [6.59]. This is a general planning trajectory strategy, which is very important to get accurate experimental identification [6.60].

6.4.3 Scaling

The numerical conditioning of parameter estimation can be improved by scaling both the output measurements (task variable scaling) and the parameters.

Task Variable Scaling

When performing a least-squares analysis on the end-point pose error, position errors and orientation errors have to be combined (6.22)

$$\|\Delta \mathbf{y}^i\|^2 = \|\Delta^{-1} \mathbf{p}_{n+1}^l\|^2 + \|\Delta^{-1} \boldsymbol{\rho}_{n+1}^l\|^2. \quad (6.94)$$

However, position error and orientation error have different units, and so are not comparable. Furthermore, not all position or orientation components may be measured with equal accuracy.

Ordinary least squares (6.8) weighs all task variables equally. To weigh these variables differently, the general solution is left multiplication of (6.7) by a scaling matrix \mathbf{G} [6.45],

$$\begin{aligned} \mathbf{G} \Delta \mathbf{y} &= \mathbf{G} \mathbf{A} \Delta \boldsymbol{\phi}, \\ \Delta \tilde{\mathbf{y}} &\equiv \tilde{\mathbf{A}} \Delta \boldsymbol{\phi}, \end{aligned} \quad (6.95)$$

where $\Delta \tilde{\mathbf{y}} = \mathbf{G} \Delta \mathbf{y}$ is the scaled output vector and $\tilde{\mathbf{A}} = \mathbf{G} \mathbf{A}$ is the scaled regressor matrix. The weighted least-squares solution is

$$\Delta \boldsymbol{\phi} = (\tilde{\mathbf{A}}^T \tilde{\mathbf{A}})^{-1} \tilde{\mathbf{A}}^T \Delta \tilde{\mathbf{y}} = (\mathbf{A}^T \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{W} \Delta \mathbf{y}, \quad (6.96)$$

where $\mathbf{W} = \mathbf{G}^T \mathbf{G}$. Often \mathbf{W} is a diagonal matrix.

One approach to scaling position error versus orientation error is to equalize the effect of a parameter error $\Delta \phi_i$ on either position error or orientation error. Curiously, for human-sized robot arms the effect is equal without scaling due to an accident of metric units. If θ is the joint angle resolution, then $s = r\theta$ is the resulting endpoint position resolution. For human-sized arms, $r = 1$ m and hence $s = \theta$. Thus meters and radians are directly comparable after all. Thus using no scaling factors for the pose parameters makes some sense, and may explain why the general disregard for scaling in the robotics community has not had more consequences. If linkages are much smaller (like fingers) or much larger (like excavators) then the situation is different.

A more general way of choosing the weighting matrix \mathbf{W} is to use a priori information about acceptable relative errors. Such information might arise from specifications of the measurement apparatus. Suppose that the output variables are subject to independent Gaussian noise, such that σ_j^y is the standard deviation in task variable measurement component Δy_j^i , for $j = 1, \dots, m$ pose components. Then the individual diagonal weights are $w_{jj} = 1/\sigma_j^y$, and define

$$\mathbf{R}^i = \text{diag} \left[(\sigma_1^y)^2, \dots, (\sigma_m^y)^2 \right],$$

$$\mathbf{R} = \text{diag}(\mathbf{R}^1, \dots, \mathbf{R}^P),$$

where the weighting matrix $\mathbf{W} = \mathbf{R}^{-1}$, and \mathbf{R} is called the *covariance matrix*.

The weighted least-squares estimate is

$$\Delta \phi = (\mathbf{A}^T \mathbf{R}^{-1} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{R}^{-1} \Delta \mathbf{y}. \quad (6.97)$$

The resulting scaled output variable $\Delta \tilde{y}_j^i = \Delta y_j^i / \sigma_j^y$ is dimensionless. The larger the uncertainty σ_j^y , the less this variable influences the least-squares solution relative to other variables. The standard deviations σ_j^y are not necessarily the same as endpoint measurement accuracy, because model errors and input noise also contribute to output errors.

The weighted least-squares solution using standard deviations is variously called the Gauss–Markov estimate, the generalized least-squares estimate, or the best linear unbiased estimator (BLUE) [6.3]. It is the minimum covariance estimate (on the parameter error) of all unbiased estimators. A significant point is that the standard deviations of the scaled components of $\Delta \tilde{\mathbf{y}}$ are all about the same size, or the covariance $\hat{\mathbf{R}} = \text{cov}(\Delta \tilde{\mathbf{y}}) = \mathbf{I}$, the identity matrix. Hence the Euclidean norm of the error vector $\Delta \tilde{\mathbf{y}}$ is a reasonable measure of its size.

Often we do not know the covariance matrix \mathbf{R} that well. An estimate of the standard deviations after running the calibration procedure is obtained from the χ^2 statistic [6.44, 46]

$$\chi^2 = (\Delta \mathbf{y} - \mathbf{A} \Delta \phi)^T \mathbf{R}^{-1} (\Delta \mathbf{y} - \mathbf{A} \Delta \phi). \quad (6.98)$$

This equation is the same as the residual error (6.95), with substitution for $\mathbf{W} = \mathbf{R}^{-1}$. χ^2 is nothing more than the weighted residuals after calibration. The expected value of χ^2 is

$$E(\chi^2) \equiv v = PK - R, \quad (6.99)$$

where E is the expectation operator. That is to say, the unweighted residuals $(\Delta \mathbf{y} - \mathbf{A} \Delta \phi)^2$ should, with enough measurements, approximate the true covariance. We may now uniformly scale an initial estimate

of \mathbf{R} after a preliminary calibration, based on the value of χ^2 ,

$$\hat{\mathbf{R}} = \frac{\chi^2}{v} \mathbf{R}, \quad (6.100)$$

where $\hat{\mathbf{R}}$ is the revised estimate of the covariance matrix.

Parameter Scaling

Scaling of parameters is important for proper convergence in nonlinear optimization and for singular value decomposition. If parameters have vastly different magnitudes, then the singular values are not directly comparable. Also, parameter scaling can improve the conditioning of the regressor \mathbf{A} and help to avoid invertibility problems.

Whereas left multiplication of \mathbf{A} in (6.95) results in task variable scaling, right multiplication of \mathbf{A} by a weighting matrix \mathbf{H} results in parameter scaling [6.45]

$$\Delta \mathbf{y} = (\mathbf{A} \mathbf{H})(\mathbf{H}^{-1} \Delta \phi) \equiv \bar{\mathbf{A}} \Delta \tilde{\phi}, \quad (6.101)$$

where the scaled Jacobian and parameters are $\bar{\mathbf{A}} = \mathbf{A} \mathbf{H}$ and $\Delta \tilde{\phi} = \mathbf{H}^{-1} \Delta \phi$. The least-squares solution is not changed by parameter scaling, whereas it is by task variable scaling.

The most common approach towards parameter weighting is column scaling, which does not require a priori statistical information. Define a diagonal matrix $\mathbf{H} = \text{diag}(h_1, \dots, h_{N_{\text{par}}})$ with elements

$$h_j = \begin{cases} \|c_j\|^{-1} & \text{if } \|c_j\| \neq 0 \\ 1 & \text{if } \|c_j\| = 0 \end{cases} \quad (6.102)$$

where c_j is the j -th column of \mathbf{A} . Then (6.101) becomes

$$\Delta \mathbf{y} = \sum_{j=1}^{N_{\text{par}}} \frac{a_j}{\|a_j\|} \Delta \phi_j \|a_j\|. \quad (6.103)$$

Suppose that $\Delta \mathbf{y}$ has been previously normalized; then its length is meaningful. Each $a_j / \|a_j\|$ is a unit vector, and hence each scaled parameter $\Delta \phi_j \|a_j\|$ is about the same size and has the same effect on $\Delta \mathbf{y}$.

Schröder [6.38] identified a problem with column scaling, namely that poor identifiability of parameters can result in very small Euclidean norms, which result in very large scaling factors. This results in strong amplification of uncertainties of \mathbf{A} . Instead, Schröder proposed scaling based on the effect on the anticipated error of the robot (as previously discussed under task variable scaling).

In an ideal case, one would have a priori knowledge of the expected value ϕ_0 of the parameter vector and the standard deviation σ_j^ϕ of each of the parameter vector components. More generally, the parameter distribution would be described by a covariance matrix \mathbf{M} , but usually this information is not available. Instead, the estimate $\hat{\mathbf{M}}$ of the covariance from (6.85) can be used.

If the output measurement covariance \mathbf{R}^{-1} and parameter error covariance \mathbf{M} are both available, one may define a new least-squares optimization criterion that combines output errors with parameter errors to yield a new χ^2 statistic

$$\chi^2 = (\Delta y - \mathbf{A}\Delta\phi)^T \mathbf{R}^{-1} (\Delta y - \mathbf{A}\Delta\phi) + \Delta\phi^T \mathbf{M}^{-1} \Delta\phi. \quad (6.104)$$

Its solution is the minimum-variance estimate, which unlike (6.97) is biased

$$\Delta\phi = (\mathbf{A}^T \mathbf{R}^{-1} \mathbf{A} + \mathbf{M}^{-1})^{-1} \mathbf{A}^T \mathbf{R}^{-1} \Delta y. \quad (6.105)$$

The Kalman filter recursively solves the same problem [6.61, 62]; when the state is nonvarying, there is a constant process, and there is no process noise [6.13, 63]. The Gauss–Markov estimate is the limiting case when \mathbf{M}^{-1} is zero, i.e., there is no a priori information about the parameters. Again, there is an issue of determining the covariances. As for the Gauss–Markov estimate, the expected value of χ^2 can be used to uniformly scale \mathbf{R} and \mathbf{M} *post facto* [6.64].

6.4.4 Recursive Least Squares and the Kalman Filter

In a control setting, it may be necessary to update the estimate $\hat{\phi}$ at time step k based upon all the readings up to time step $k-1$. It is possible to recast least squares recursively to perform this updating [6.3], which is strongly analogous to the Kalman Filter. At time step k , there is a new reading

$$y^k = \mathbf{A}^k \phi + e^k, \quad (6.106)$$

where y^k is of dimension $M \times 1$, \mathbf{A}^k is of dimension $M \times N$, and ϕ is of dimension $N \times 1$. Let \mathbf{R}^k be the covariance of e^k . This equation is stacked for all readings up to k , and the Gauss–Markov estimate is derived

$$y_k = \mathbf{A}_k \phi + e_k \\ \hat{\phi}_k = (\mathbf{A}_k^T \mathbf{R}_k^{-1} \mathbf{A}_k)^{-1} \mathbf{A}_k^T \mathbf{R}_k^{-1} y_k, \quad (6.107)$$

where y_k is of dimension $MK \times 1$, and \mathbf{A}_k is of dimension $MK \times N$. \mathbf{R}_k is the covariance of e_k , and is a block-diagonal matrix with elements \mathbf{R}^k .

To make an analogy to the Kalman filter, define the covariance of $\hat{\phi}$ as $\mathbf{P}_k = (\mathbf{A}_k^T \mathbf{R}_k^{-1} \mathbf{A}_k)^{-1}$ of dimension $N \times N$. Inverting this relation eventually yields a recursive relationship in terms of the covariance up to the previous time, step, plus a new contribution

$$\mathbf{P}_k^{-1} = \mathbf{P}_{k-1}^{-1} + (\mathbf{A}^k)^T (\mathbf{R}^k)^{-1} \mathbf{A}^k. \quad (6.108)$$

Similarly,

$$\mathbf{A}_k^T \mathbf{R}_k^{-1} y_k = \mathbf{A}_{k-1}^T \mathbf{R}_{k-1}^{-1} y_{k-1} + (\mathbf{A}^k)^T (\mathbf{R}^k)^{-1} y^k. \quad (6.109)$$

Substituting the definition of \mathbf{P}_k and (6.109) into (6.107) eventually yields

$$\hat{\phi}_k = \hat{\phi}_{k-1} + \mathbf{P}_k (\mathbf{A}^k)^T (\mathbf{R}^k)^{-1} (y^k - \mathbf{A}^k \hat{\phi}_{k-1}). \quad (6.110)$$

In the covariance updating matrix (6.108), the inverse \mathbf{P}_{k-1}^{-1} has to be taken. The updating relationship can be reworked into a computationally friendlier form using the binomial inverse theorem (see Wikipedia entry)

$$(\mathbf{A} + \mathbf{UBV})^{-1} = \mathbf{A}^{-1} - \mathbf{A}^{-1} \mathbf{U} (\mathbf{B}^{-1} + \mathbf{VA}^{-1} \mathbf{U})^{-1} \mathbf{VA}^{-1} \quad (6.111)$$

Making the identification $\mathbf{A} = \mathbf{P}_{k-1}^{-1}$, $\mathbf{U} = (\mathbf{A}^k)^T$, $\mathbf{B} = (\mathbf{R}^k)^{-1}$, and $\mathbf{V} = \mathbf{A}^k$, after inversion (6.108) becomes

$$\mathbf{P}_k = \mathbf{P}_{k-1} - \mathbf{P}_{k-1} (\mathbf{A}^k)^T (\mathbf{R}^k + \mathbf{A}^k \mathbf{P}_{k-1} (\mathbf{A}^k)^T)^{-1} \mathbf{A}^k \mathbf{P}_{k-1} \quad (6.112)$$

The resulting matrix in parentheses is of size $M \times M$, and is typically of much lower dimension than the $N \times N$ dimension of \mathbf{P}_k . That is to say, there are usually many more parameters than measurement components. Hence the inversion is easier.

Equations (6.110) and (6.112) comprise a large part of the Kalman filter. Thus the Kalman filter is fundamentally recursive least squares [6.3, 61, 62]. There are many variants to the Kalman filter, including one based on the mmse estimate.

Gautier and Poignet [6.65] applied an extended Kalman filter to estimate a robot's inertial parameters, in which the filter was reworked to include velocity and acceleration estimation. They found that there was no advantage to using a Kalman filter over least squares, and in fact there was a disadvantage in terms of sensitivity to initial conditions and slower

convergence. One issue in on-line versus off-line estimation is the accuracy of velocity and acceleration estimates. In off-line estimation, two sided (or acausal)

filters can be used, and they typically estimate time derivatives more accurately than one-side (or causal) filters.

6.5 Conclusions and Further Reading

This chapter has presented methods for calibrating the kinematic parameters and the inertial parameters of robot manipulators. Both methods are instances of parameter estimation using least squares. Inertial parameters appear linearly in the equations of motion, and ordinary least squares can be used. Kinematic parameters appear nonlinearly because of sines and cosines, and so nonlinear estimation via the Gauss–Newton method can be applied.

There are domain-specific issues for setting up the calibration equations. For kinematic calibration, Denavit–Hartenberg parameters have to be mixed with Denavit–Hartenberg parameters to handle the case of nearly parallel joint axes. The calibration equations have to take into account how the endpoint is measured or constrained. By examining in a detailed fashion the possible joint sequences, including parallel or prismatic joints, a minimal parameterization is achieved that obviates problems of identifiability.

The calibration index has been presented as categorizing all kinematic calibration methods. This index counts the number of equations generated per pose, by calculating the excess of sensing over mobility. A key is that all calibration methods can be viewed as closed-loop methods, where any endpoint sensing system is considered as a joint. Parallel robots are handled by incorporating multiple closed loops.

For inertial parameter estimation, the recursive Newton–Euler equations lead to a formulation of the regressor matrix as an upper-diagonal matrix. A minimal parameterization is straightforward for serial and spanning robots. The load inertial parameters estimation has been treated by using either the joint torques or the terminal link force-torque sensor measurements. The proposed models are exploited to identify the joint torques gains supposing known load parameters.

Numerical methods were presented to handle unidentifiable parameters if a minimal parameterization has not been achieved. These methods hinge on the singular value or QR decomposition of the regressor matrix. The singular values can be examined to decide which parameters are not identifiable and should be eliminated. Alternatively, a small singular value can simply be zeroed to eliminate the effects of poorly identifiable parameters without explicitly eliminating them. The former yields a structural model, while the latter

yields a prediction model. A priori estimates of parameters can be taken into account by using damped least squares.

The adequacy of the measurement set for parameter estimation is captured by different proposals for an observability index. This index can be related to the literature on alphabet optimalities in experimental design.

Finally, the scaling of measurements or of parameters is important for a well-conditioned numerical estimation, and is essential in order to compare singular values. When uncertainties in measurements and in parameters are included as weights, the optimal minimum variance estimate can be found, which is related to the Kalman filter. If not known beforehand, these uncertainties can be estimated from the data.

6.5.1 Relation to Other Chapters

Estimation involving least squares and Kalman filtering is discussed in Chap. 5 in a similar context. The problem of estimating properties of the world through sensors is very similar to model identification. Recursive estimation techniques are particularly appropriate when a robot needs to update its world model incrementally. For model identification, employing a recursive formulation is not particularly helpful, as the machinery of recursive updating can obscure numerical issues with the total data.

The singular value decomposition appears in other contexts. Chapter 10 and 16 analyze equal motion capability in different directions by measures similar to the observability indexes: O_1 has a counterpart in the manipulability measure, and O_2 the condition number and O_3 the minimum singular value appear again. By contrast, the concern in calibration is good data in all directions as captured by the singular values. Chap. 10 employs the singular value decomposition to analyze redundant mechanisms. Whereas parameter estimation generally is an overconstrained least-squares problem (many more measurements than parameters), redundant mechanisms are underconstrained (more joint angles than task variables). Instead of signalling identifiability problems, zero singular values indicate the null space of the Jacobian. Damped least squares is used in Chap. 10 to avoid singularities. Just as the true parameters are perturbed by damped least squares in calibration, the

trajectory is perturbed in order to get around a numerical conditioning issue.

Sensors involved in positioning a robot can have aspects of their sensor models calibrated as well, such as the gain of a potentiometer. Camera calibration is discussed in Chap. 32. Camera models can be determined at the same time as the kinematic models of robot manipulators [6.39, 66], including intrinsic camera parameters such as the pinhole model discussed in Chap. 5 as well as the extrinsic parameters of where the camera is located.

6.5.2 Further Reading

Screw Axis Measurement

An alternative to nonlinear least squares to estimate kinematic parameters is a class of methods which measure the joint axes as lines in space, termed *screw axis measurement* in [6.8]. One approach is *circle point analysis*, which involves moving one joint at a time to generate a circle at a distal measurement point [6.13]. Other approaches measure the Jacobian matrix, which contains as columns the joint screws [6.67]. With knowledge of the joint axes, the kinematic parameters are straightforwardly extracted without nonlinear search. The accuracy of this class of methods may not be as good as the nonlinear least-squares methods.

Total Least Squares

Ordinary least squares assumes that there is only noise in the output measurements, but often there is noise in the inputs as well. Input noise is known to lead to bias errors [6.3]. A framework for handling both

input and output noise is total least squares [6.34], also known as orthogonal distance regression [6.68] or errors-in-variables regression [6.69]. Nonlinear total least squares has been applied to robot calibration in [6.2, 70, 71]. In the implicit loop method of [6.2], by treating endpoint measurements equally with joint measurements, no distinction is made between input and output noise.

Methods with Direct and Inverse Dynamic Models

The identification of dynamic parameters presented in this chapter is based on the Inverse Dynamic Identification Model and linear LS techniques. A common procedure to validate the identification result is to simulate the direct dynamic model with the identified parameters and compare the output with the real system.

Recently two methods which use both the direct and the inverse dynamic models have been developed to improve the noise immunity of estimates with respect to low rate or corrupted data in the observation matrix resulting from noisy measurements and/or bad tuning of joint positions band-pass filtering. The first method needs only the joint torques, while the velocity and acceleration are obtained from the direct dynamic model. It carries out in a combined procedure the identification and the validation. Current work aims to use this technique to identify robots with flexible joints where the flexible position variables are not measurable. The second method uses an instrumental variable (IV) approach. Both methods have been validated on a 6-DOF industrial robot [6.72, 73].

7. Motion Planning

Lydia E. Kavraki, Steven M. LaValle

This chapter first provides a formulation of the geometric path planning problem in Sect. 7.2 and then introduces sampling-based planning in Sect. 7.3. Sampling-based planners are general techniques applicable to a wide set of problems and have been successful in dealing with hard planning instances. For specific, often simpler, planning instances, alternative approaches exist and are presented in Sect. 7.4. These approaches provide theoretical guarantees and for simple planning instances they outperform sampling-based planners. Section 7.5 considers problems that involve differential constraints, while Sect. 7.6 overviews several other extensions of the basic problem formulation and proposed solutions. Finally, Sect. 7.8 addresses some important and more advanced topics related to motion planning.

7.1 Robotics Motion Planning

A fundamental robotics task is to plan collision-free motions for complex bodies from a start to a goal position among a collection of static obstacles. Although relatively simple, this geometric path planning problem is computationally hard [7.1]. Extensions of this formulation take into account additional problems

that are inherited from mechanical and sensor limitations of real robots such as uncertainties, feedback, and differential constraints, which further complicate the development of automated planners. Modern algorithms have been fairly successful in addressing hard instances of the basic geometric problem and

a lot of effort has been devoted to extend their capabilities to more challenging instances. These algorithms have had widespread success in applications beyond robotics, such as computer animation, vir-

tual prototyping, and computational biology. There are many available surveys [7.2–4] and books [7.5–7] that cover modern motion planning techniques and applications.

7.2 Motion Planning Concepts

This section provides a description of the fundamental motion planning problem or the geometric path planning problem. Extensions of this basic formulation to more complicated instances will be discussed later in the chapter and will be revisited throughout this book.

7.2.1 Configuration Space

In path planning, a complete description of the geometry of a robot \mathcal{A} and of a workspace \mathcal{W} is provided. The workspace $\mathcal{W} = \mathbb{R}^N$, in which $N = 2$ or $N = 3$, is a static environment populated with obstacles. The goal is to find a collision-free path for \mathcal{A} to move from an initial position and orientation to a goal position and orientation.

To achieve this, a complete specification of the location of every point on the robot geometry, or a *configuration* \mathbf{q} , must be provided. The *configuration space*, or C-space ($\mathbf{q} \in C$), is the space of all possible configurations. The C-space represents the set of all transformations that can be applied to a robot given its kinematics as described in Chap. 2 (Kinematics). It was recognized early on in motion planning research [7.8,9] that the C-space is a useful way to abstract planning problems in a unified way. The advantage of this abstraction is that a robot with a complex geometric shape is mapped to a single point in the C-space. The number of degrees of freedom of a robot system is the dimension of the C-space, or the minimum number of parameters needed to specify a configuration.

Let the closed set $\mathcal{O} \subset \mathcal{W}$ represent the (*workspace*) *obstacle region*, which is usually expressed as a collection of polyhedra, three-dimensional (3-D) triangles, or piecewise-algebraic surfaces. Let the closed set $\mathcal{A}(\mathbf{q}) \subset \mathcal{W}$ denote the set of points occupied by the robot when at configuration $\mathbf{q} \in C$; this set is usually modeled using the same primitives as used for \mathcal{O} . The *C-space obstacle region*, C_{obs} , is defined as

$$C_{\text{obs}} = \{\mathbf{q} \in C \mid \mathcal{A}(\mathbf{q}) \cap \mathcal{O} \neq \emptyset\}. \quad (7.1)$$

Since \mathcal{O} and $\mathcal{A}(\mathbf{q})$ are closed sets in \mathcal{W} , the obstacle region is a closed set in C . The set of configurations that avoid collision is $C_{\text{free}} = C \setminus C_{\text{obs}}$, and is called the *free space*.

Simple Examples of C-spaces

Translating Planar Rigid Bodies. The robot's configuration can be specified by a reference point (x, y) on the planar rigid body relative to some fixed coordinate frame. Therefore the C-space is equivalent to \mathbb{R}^2 . Figure 7.1 gives an example of a C-space for a triangular robot and a single polygonal obstacle. The obstacle region in the C-space can be traced by sliding the robot around the workspace obstacle to find the constraints on all $\mathbf{q} \in C$. Motion planning for the robot is now equivalent to motion planning for a point in the C-space.

Planar Arms. Figure 7.2 gives an example of a two-joint planar arm. The bases of both links are pinned, so that they can only rotate around the joints, and there are no joint limits. For this arm, specifying the rotational parameters θ_1 and θ_2 provides the configuration. Each joint angle θ_i corresponds to a point on the unit circle \mathbb{S}^1 and the C-space is $\mathbb{S}^1 \times \mathbb{S}^1 = T^2$, the two-dimensional (2-D) torus shown in Fig. 7.2. For a higher number of

Fig. 7.1a,b A robot translating in the plane: (a) a triangular robot moves in a workspace with a single rectangular obstacle. (b) The C-space obstacle

Fig. 7.2 (a) A two-joint planar arm in which the links are pinned and there are no joint limits. (b) The C-space

links without joint limits, the C-space can be similarly defined as

$$C = \mathbb{S}^1 \times \mathbb{S}^1 \times \dots \times \mathbb{S}^1. \quad (7.2)$$

If a joint has limits, then each corresponding \mathbb{S}^1 is often replaced with \mathbb{R} , even though it is a finite interval. If the base of the planar arm is mobile and not pinned, then the additional translation parameters must also be considered in the arm's configuration

$$C = \mathbb{R}^2 \times \mathbb{S}^1 \times \mathbb{S}^1 \times \dots \times \mathbb{S}^1. \quad (7.3)$$

Additional examples of C-spaces are provided in Sect. 7.7.1, where topological properties of configuration spaces are discussed.

7.2.2 Geometric Path Planning Problem

The basic motion planning problem, also known as the *piano mover's problem* [7.1], is defined as follows.

Given:

1. A *workspace* \mathcal{W} , where either $\mathcal{W} = \mathbb{R}^2$ or $\mathcal{W} = \mathbb{R}^3$.
2. An *obstacle region* $\mathcal{O} \subset \mathcal{W}$.
3. A *robot* defined in \mathcal{W} . Either a rigid body \mathcal{A} or a collection of m links: $\mathcal{A}_1, \mathcal{A}_2, \dots, \mathcal{A}_m$.
4. The *configuration space* C (C_{obs} and C_{free} are then defined).
5. An *initial configuration* $\mathbf{q}_I \in C_{\text{free}}$.
6. A *goal configuration* $\mathbf{q}_G \in C_{\text{free}}$. The initial and goal configuration are often called a *query* $(\mathbf{q}_I, \mathbf{q}_G)$.

Compute a (continuous) path, $\tau: [0, 1] \rightarrow C_{\text{free}}$, such that $\tau(0) = \mathbf{q}_I$ and $\tau(1) = \mathbf{q}_G$.

7.2.3 Complexity of Motion Planning

The main complications in motion planning are that it is not easy to directly compute C_{obs} and C_{free} , and the dimensionality of the C-space is often quite high. In terms of computational complexity, the piano mover's problem was studied early on and it was shown to be PSPACE-hard by Reif [7.1]. A series of polynomial-

time algorithms for problems with fixed dimension suggested an exponential dependence on the problem dimensionality [7.10, 11]. A single exponential-time algorithm in the C-space dimensionality was proposed by Canny and showed that the problem is PSPACE-complete [7.12]. Although impractical, the algorithm serves as an upper bound on the general version of the basic motion planning problem. It applies computational algebraic geometry techniques for modeling the C-space in order to construct a *roadmap*, a one-dimensional (1-D) subspace that captures the connectivity of C_{free} . Additional details about such techniques can be found in Sect. 7.7.3.

The complexity of the problem motivated work in path planning research. One direction was to study subclasses of the general problem for which polynomial time algorithms exist [7.13]. Even some simpler, special cases of motion planning, however, are at least as challenging, for example, the case of a finite number of translating, axis-aligned rectangles in \mathbb{R}^2 is PSPACE-hard as well [7.14]. Some extensions of motion planning are even harder. For example, a certain form of planning under uncertainty in 3-D polyhedral environment is NEXPTIME-hard [7.15]. The hardest problems in NEXPTIME are believed to require doubly exponential time to solve.

A different direction was the development of alternative planning paradigms that were practical under realistic assumptions. Many combinatorial approaches can efficiently construct 1-D roadmaps for specific 2-D or 3-D problems. Potential field-based approaches define vector fields which can be followed by a robot towards the goal. Both approaches, however, do not scale well in the general case. They will be described in Sect. 7.4. An alternative paradigm, sampling-based planning, is a general approach that has been shown to be successful in practice for many challenging problems. It avoids the exact geometric modeling of the C-space but it cannot provide the guarantees of a complete algorithm. Complete and exact algorithms are able to detect that no path can be found. Instead sampling-based planning offers a lower level of completeness guarantee. This paradigm is described in the following section.

7.3 Sampling-Based Planning

Sampling-based planners are described first because they are the method of choice for a very general class of problems. The following section will describe other planners, some of which were developed before the sampling-based framework. The key idea in sampling-based planning is to exploit advances in collision detection algorithms that compute whether a single con-

figuration is collision free. Given this simple primitive, a planner samples different configurations to construct a data structure that stores 1-D C-space curves, which represent collision-free paths. In this way, sampling-based planners do not access the C-space obstacles directly but only through the collision detector and the constructed data structure. Using this level of abstrac-

tion, the planners are applicable to a wide range of problems by tailoring the collision detector to specific robots and applications.

A standard for sampling-based planners is to provide a weaker, but still interesting, form of completeness: *if a solution path exists, the planner will eventually find it*. Giving up on the stronger form of completeness, which also requires failure to be reported in finite time, these techniques are able to solve in practice problems with more than three degrees of freedom that complete approaches cannot address. More details on this weaker form of completeness are provided in Sect. 7.7.2.

Different planners follow different approaches on how to sample configurations and what kind of data structures they construct. Section 7.7.2 provides a deeper insight on sampling issues. A typical classification of sampling-based planners is between multi-query and single-query approaches:

- In the first category, the planners construct a roadmap, an undirected graph G that is precomputed once so as to *map the connectivity properties of C_{free}* . After this step, multiple queries in the same environment can be answered using only the constructed roadmap. Such planners are described in Sect. 7.3.1.
- Planners in the second category build tree data structures on the fly given a planning query. They attempt to focus on exploring the part of the C -space that will lead to solving a specific query as fast as possible. They are described in Sect. 7.3.2.

Both approaches, however, make similar use of a collision checking primitive. The objective of a collision detector is to report all geometric contacts between objects given their geometries and transformations [7.16–18]. The availability of packages that were able to answer collision queries in a fraction of a second was critical to the development of sampling-based planners. Modern planners use collision detectors as a *black box*. Initially the planner provides the geometries of all the involved objects and specifies which of them are mobile. Then, in order to validate a robot configuration, a planner provides the corresponding robot transformation and a collision detector responds on whether the objects collide or not. Many packages represent the geometric models hierarchically, avoid computing all-pairwise interactions, and conduct a binary search to evaluate collisions. Except from configurations, a planner must also validate entire paths. Some collision detectors return distance-from-collision information, which can be used to infer that entire neighborhoods in C are valid. It is often more expensive, however, to extract this information; instead

paths are usually validated point by point using a small stepping size either incrementally or by employing binary search. Some collision detectors are incremental by design, which means that they can be faster by reusing information from a previous query [7.16]. Examples of problems solved by sampling-based planners are shown in  VIDEO 24 and  VIDEO 17.

7.3.1 Multi-Query Planners: Mapping the Connectivity of C_{free}

Planners that aim to answer multiple queries for a certain static environment use a preprocessing phase during which they attempt to map the connectivity properties of C_{free} onto a roadmap. This roadmap has the form of a graph G , with vertices as configurations and edges as paths. A union of 1-D curves is a roadmap G if it satisfies the following properties:

1. *Accessibility*: From any $q \in C_{\text{free}}$, it is simple and efficient to compute a path $\tau : [0, 1] \rightarrow C_{\text{free}}$ such that $\tau(0) = q$ and $\tau(1) = s$, in which s may be any point in $S(G)$. $S(G)$ is the *swath* of G , the union of all configurations reached by all edges and vertices. This means that it is always possible to connect a planning query pair q_I and q_G to some s_I and s_G , respectively, in $S(G)$.
2. *Connectivity preserving*: The second condition requires that, if there exists a path $\tau : [0, 1] \rightarrow C_{\text{free}}$ such that $\tau(0) = q_I$ and $\tau(1) = q_G$, then there also exists a path $\tau' : [0, 1] \rightarrow S(G)$, such that $\tau'(0) = s_I$ and $\tau'(1) = s_G$. Thus, solutions are not missed because G fails to capture the connectivity of C_{free} .

The probabilistic roadmap method (PRM) approach [7.19] attempts to approximate such a roadmap G in a computationally efficient way. The preprocessing phase of PRM, which can be extended to sampling-based roadmaps in general, follows these steps:

1. *Initialization*: Let $G(V, E)$ represent an undirected graph, which is initially empty. Vertices of G will correspond to collision-free configurations, and edges to collision-free paths that connect vertices.
2. *Configuration sampling*: A configuration $\alpha(i)$ is sampled from C_{free} and added to the vertex set V . $\alpha(\cdot)$ is an infinite, dense sample sequence and $\alpha(i)$ is the i -th point in that sequence.
3. *Neighborhood computation*: Usually, a metric is defined in the C -space, $\rho : C \times C \rightarrow \mathbb{R}$. Vertices q already in V are then selected as part of $\alpha(i)$'s neighborhood if they have small distance according to ρ .
4. *Edge consideration*: For those vertices q that do not belong in the same connected component of G with

$\alpha(i)$ the algorithm attempts to connect them with an edge.

5. *Local planning method:* Given $\alpha(i)$ and $q \in C_{\text{free}}$ a module is used that attempts to construct a path $\tau_s : [0, 1] \rightarrow C_{\text{free}}$ such that $\tau(0) = \alpha(i)$ and $\tau(1) = q$. Using collision detection, τ_s must be checked to ensure that it does not cause a collision.
6. *Edge insertion:* Insert τ_s into E , as an edge from $\alpha(i)$ to q .
7. *Termination:* The algorithm is typically terminated when a predefined number of collision-free vertices N has been added in the roadmap.

The algorithm is incremental in nature. Computation can be repeated by starting from an already existing graph. A general sampling-based roadmap is summarized in Algorithm 7.1.

Algorithm 7.1 Sampling-Based Roadmap

N : number of nodes to include in the roadmap

```

1:  $G.\text{init}()$ ;  $i \leftarrow 0$ ;
2: while  $i < N$  do
3:   if  $\alpha(i) \in C_{\text{free}}$  then
4:      $G.\text{add\_vertex}(\alpha(i))$ ;  $i \leftarrow i + 1$ ;
5:   for  $q \in \text{NEIGHBORHOOD}(\alpha(i), G)$  do
6:     if  $\text{CONNECT}(\alpha(i), q)$  then
7:        $G.\text{add\_edge}(\alpha(i), q)$ ;
8:     end if
9:   end for
10:  end if
11: end while

```

An illustration of the algorithm's behavior is depicted in Fig. 7.3. To solve a query, q_I and q_G are connected to the roadmap, and graph search is performed.

For the original PRM [7.19], the configuration $\alpha(i)$ was produced using random sampling. For the connec-

Fig. 7.3 The sampling-based roadmap is constructed incrementally by attempting to connect each new sample, $\alpha(i)$, to nearby vertices in the roadmap

tion step between q and $\alpha(i)$, the algorithm used straight line paths in the C-space. In some cases a connection was attempted if q and $\alpha(i)$ were in the same connected component in order to improve path quality. There have been many subsequent works that try to improve the roadmap quality while using fewer samples. Methods for concentrating samples at or near the boundary of C_{free} are presented in [7.20, 21]. Methods that move samples as far from the boundary as possible appear in [7.22, 23]. Deterministic sampling techniques, including grids, appear in [7.24]. A method of pruning vertices based on mutual visibility that leads to a dramatic reduction in the number of roadmap vertices appears in [7.25]. Theoretical analysis of sampling-based roadmaps appears in [7.24, 26, 27] and is briefly discussed in Sect. 7.7.2. An experimental comparison of sampling-based roadmap variants appears in [7.28]. One difficulty in these roadmap approaches is identifying narrow passages. One proposal is to use the *bridge test* for identifying these [7.29]. For other PRM-based works, see [7.30–34]. Extended discussion of the topic can be found in [7.5, 7].

7.3.2 Single-Query Planners: Incremental Search

Single-query planning methods focus on a single initial-goal configuration pair. They probe and search the continuous C-space by extending tree data structures initialized at these known configurations and eventually connecting them. Most single-query methods conform to the following template:

1. *Initialization:* Let $G(V, E)$ represent an undirected search graph, for which the vertex set V contains a vertex for one (usually q_I) or more configurations in C_{free} , and the edge set E is empty. Vertices of G are collision-free configurations, and edges are collision-free paths that connect vertices.
2. *Vertex selection method:* Choose a vertex $q_{\text{cur}} \in V$ for expansion.
3. *Local planning method:* For some $q_{\text{new}} \in C_{\text{free}}$, which may correspond to an existing vertex in V but on a different tree or a sampled configuration, attempt to construct a path $\tau_s : [0, 1] \rightarrow C_{\text{free}}$ such that $\tau(0) = q_{\text{cur}}$ and $\tau(1) = q_{\text{new}}$. Using collision detection, τ_s must be checked to ensure that it does not cause a collision. If this step fails to produce a collision-free path segment, then go to Step 2.
4. *Insert an edge in the graph:* Insert τ_s into E , as an edge from q_{cur} to q_{new} . If q_{new} is not already in V , then it is inserted.
5. *Check for a solution:* Determine whether G encodes a solution path.

6. *Return to Step 2:* Iterate unless a solution has been found or some termination condition is satisfied, in which case the algorithm reports failure.

During execution, G may be organized into one or more trees. This leads to:

1. *Unidirectional* methods, which involve a single tree, usually rooted at q_1 [7.35],
2. *Bidirectional* methods, which involve two trees, typically rooted at q_1 and q_G [7.35], and
3. *Multidirectional* methods, which may have more than two trees [7.36, 37].

The motivation for using more than one tree is that a single tree may become trapped trying to find an exit through a narrow opening. Traveling in the opposite direction, however, may be easier. As more trees are considered it becomes more complicated to determine which connections should be made between trees.

Rapidly Exploring Dense Trees

The important idea with this family of techniques is that the algorithm must incrementally explore the properties of the C -space. An algorithm that achieves this objective is the rapidly exploring random tree (**RRT**) [7.35], which can be generalized to the rapidly exploring dense tree (**RDT**) for any dense sampling, deterministic or random [7.7]. The basic idea is to induce a *Voronoi bias* in the exploration process by selecting for expansion the point in the tree that is closest to $\alpha(i)$ in each iteration. Using random samples, the probability that a vertex is chosen is proportional to the volume of its Voronoi region. The tree construction is outlined as:

Algorithm 7.2 Rapidly Exploring Dense Trees

k : the exploration steps of the algorithm

- 1: $G.\text{init}(q_1)$;
- 2: **for** $i = 1$ **to** k **do**
- 3: $G.\text{add_vertex}(\alpha(i))$;
- 4: $q_n \leftarrow \text{NEAREST}(S(G), \alpha(i))$;
- 5: $G.\text{add_edge}(q_n, \alpha(i))$;
- 6: **end for**

The tree starts at q_1 , and in each iteration, an edge and vertex are added (Fig. 7.4).

Fig. 7.4 If there is an obstacle, the edge travels up to the obstacle boundary, as far as allowed by the collision detection algorithm

So far, the problem of reaching q_G has not been explained. There are several ways to use **RDTs** in a planning algorithm. One approach is to bias $\alpha(i)$ so that q_G is frequently chosen (perhaps once every 50 iterations). A more efficient approach is to develop a bidirectional search by growing two trees, one from each of q_1 and q_G . Roughly half of the time is spent expanding each tree in the usual way, while the other half is spent attempting to connect the trees. The simplest way to connect trees is to let the newest vertex of one tree be a substitute for $\alpha(i)$ in extending the other. This tricks one **RDT** into attempting to connect to the other while using the basic expansion algorithm [7.38]. Several works have extended, adapted, or applied **RDTs** in various applications [7.37, 39–42]. Detailed descriptions can be found in [7.5, 7].

Other Tree Algorithms

Planners based on the idea of expansive spaces are presented in [7.43–45]. In this case, the algorithm forces exploration by choosing vertices for expansion that have fewer points in a neighborhood around them. In [7.46], additional performance is obtained by self-tuning random walks, which focus virtually all of their effort on exploration. Other successful tree-based algorithms include the path-directed subdivision tree algorithm [7.47] and some of its variants [7.48]. In the literature, it is sometimes hard to locate tree-based planners for ordinary path planning problems as many of them (including **RRT**) were designed and/or applied to more complex problems (Sect. 7.5.4). Their performance is nevertheless excellent for a variety of path planning problems.

7.4 Alternative Approaches

Alternative approaches to the sampling-based paradigm include potential-field-based techniques and combinatorial methods that also produce roadmaps, such as cell

decompositions. These algorithms are able to elegantly and efficiently solve a narrow class of problems, and are much preferred over the algorithms of Sect. 7.3 in

these cases. Most of the combinatorial algorithms are of theoretical interest, whereas sampling-based algorithms are motivated primarily by performance issues in challenging applications. Nevertheless, given some abstractions, the combinatorial algorithms can be used to solve practical problems such as autonomous navigation of mobile planar robots.

7.4.1 Combinatorial Roadmaps

Several algorithms exist for the case in which $C = \mathbb{R}^2$ and C_{obs} is polygonal. Most of these cannot be directly extended to higher dimensions; however, some of the general principles remain the same. The *maximum clearance roadmap* (or *retraction method* [7.49]) constructs a roadmap that keeps paths as far from the obstacles as possible. Paths are contributed to the roadmap from the three cases shown in Fig. 7.5, which correspond to all ways to pair together polygon features. The roadmap can be made naively in time $O(n^4)$ by generating all curves shown in Fig. 7.5 for all possible pairs, computing their intersections, and tracing out the roadmap. Several algorithms exist that provide better asymptotic running time [7.50], but they are considerably more difficult to implement. The best-known algorithm runs in $O(n \lg n)$ time in which n is the number of roadmap curves [7.51].

An alternative is to compute a *shortest-path roadmap* [7.52], as shown in Fig. 7.6. This is different than the roadmap presented in the previous section because paths may actually touch the obstacles, which must be allowed for paths to be optimal. The roadmap vertices are the reflex vertices of C_{obs} , which are vertices for which the interior angle is greater than π . An edge exists in the roadmap if and only if a pair of vertices is mutually visible and the line through them pokes into C_{free} when extended outward from each vertex (such lines are called *bitangents*). An $O(n^2 \lg n)$ -time construction algorithm can be formed by using a radial sweep algorithm from each reflex vertex. It can theoretically be computed in time $O(n^2 + m)$, in which m is the total number of edges in the roadmap [7.53].

Fig. 7.5 Voronoi roadmap pieces are generated in one of three possible cases. The third case leads to a quadratic curve

Figure 7.7 illustrates the *vertical cell decomposition* approach. The idea is to decompose C_{free} into cells that are trapezoids or triangles. Planning in each cell is trivial because it is convex. A roadmap is made by placing a point in the center of each cell and each boundary between cells. Any graph search algorithm can be used to find a collision-free path quickly. The cell decomposition can be constructed in $O(n \lg n)$ time using the *plane-sweep principle* [7.54, 55]. Imagine that a vertical line sweeps from $x = -\infty$ to $x = \infty$, stopping at places where a polygon vertex is encountered. In these cases, a cell boundary may be necessary above and/or below the vertex. The order in which segments stab the vertical line is maintained in a balanced search tree. This enables the determination of the vertical cell boundary limits in time $O(\lg n)$. The whole algorithm runs in time $O(n \lg n)$ because there are $O(n)$ vertices at which the sweep line can stop (also, the vertices need to be sorted at the outset, which requires time $O(n \lg n)$).

Fig. 7.6 The shortest-path roadmap includes edges between consecutive reflex vertices on C_{obs} and also bitangent edges

Fig. 7.7 The roadmap derived from the vertical cell decomposition

7.4.2 Roadmaps in Higher Dimensions

It would be convenient if the methods of Sect. 7.4.1 directly extend into higher dimensions. Although this unfortunately does not occur, some of the general ideas extend. To consider a cell decomposition in higher dimensions, there are two main requirements: (1) each cell should be simple enough that motion planning within a cell is trivial; (2) the cells should fit together nicely. A sufficient condition for the first requirement is that cells are convex; more general shapes may be allowed; however, the cells should not contain holes under any circumstances. For the second requirement, a sufficient condition is that the cells can be organized into a *singular complex*. This means that for any two d -dimensional cells for $d \leq n$, if the boundaries of the cells intersect, then the common boundary must itself be a complete cell (of lower dimension).

In two-dimensional polygonal C-spaces, triangulation methods define nice cell decompositions that are appropriate for motion planning. Finding good triangulations, which for example means trying to avoid thin triangles, is given considerable attention in computational geometry [7.55]. Determining the decomposition of a polygonal obstacle region with holes that uses the smallest number of convex cells is *NP-hard* [7.56]. Therefore, we are willing to tolerate nonoptimal decompositions.

In three-dimensional C-spaces, if C_{obs} is polyhedral, then the vertical decomposition method directly extends by applying the plane sweep recursively, for example, the critical events may occur at each z coordinate, at which point changes a 2-D vertical decomposition over the x and y coordinates are maintained. The polyhedral case is obtained for a translating polyhedral robot among polyhedral obstacles in \mathbb{R}^3 ; however, for most interesting problems, C_{obs} becomes nonlinear. Suppose $C = \mathbb{R}^2 \times \mathbb{S}^1$, which corresponds to a robot that can translate and rotate in the plane. Suppose the robot and obstacles are polygonal. For the case of a line-segment robot, an $O(n^5)$ algorithm that is not too difficult to implement is given in [7.57]. The approaches for more general models and C-spaces are extremely difficult to use in practice; they are mainly of theoretical interest and are summarized in Sect. 7.7.3.

7.4.3 Potential Fields

A different approach for motion planning is inspired from obstacle avoidance techniques [7.58]. It does not explicitly construct a roadmap, but instead constructs a differentiable real-valued function $U: \mathbb{R}^m \rightarrow \mathbb{R}$, called a potential function, that guides the motion of the moving object. The potential is typically

constructed so that it consists of an attractive component $U_a(q)$, which pulls the robot towards the goal, and a repulsive component $U_r(q)$, which pushes the robot away from the obstacles, as shown in Fig. 7.8. The gradient of the potential function is the vector $\nabla U(q) = DU(q)^T = [\frac{\partial U}{\partial q_1}(q), \dots, \frac{\partial U}{\partial q_m}(q)]^T$, which

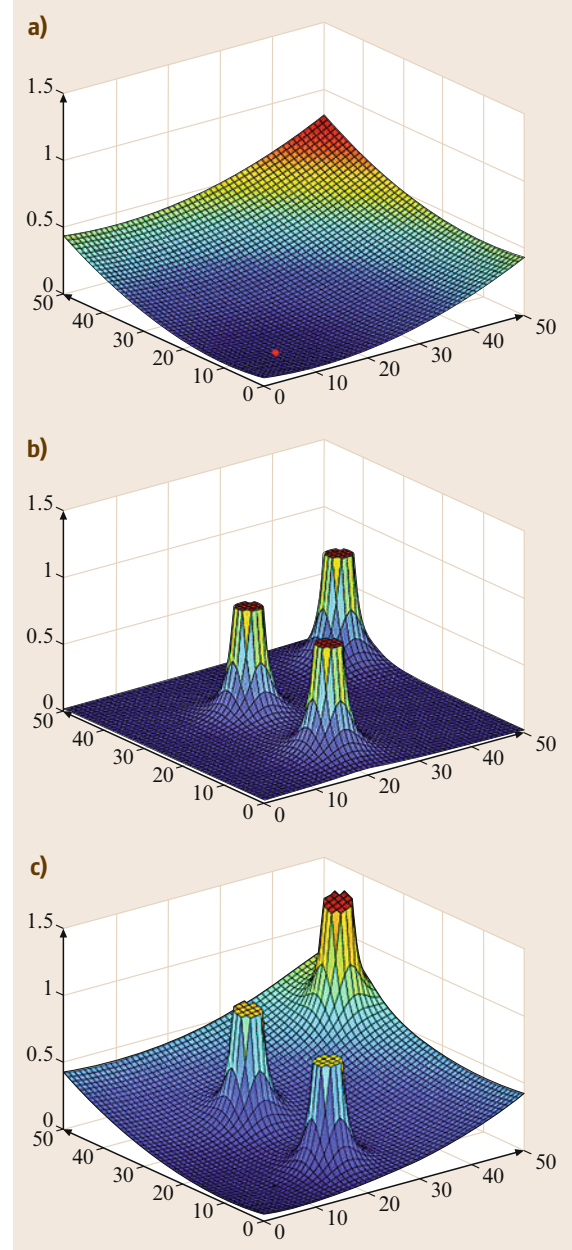

Fig.7.8a–c An attractive and a repulsive component define a potential function. (a) An attractive potential, (b) a repulsive potential, (c) an attractive and repulsive component define a potential function

points in the direction that locally maximally increases U . After the definition of U , a path can be computed by starting from q_1 and applying *gradient descent*:

1. $q(0) = q_1; i = 0;$
2. **while** $\nabla U(q(i)) \neq 0$ **do**
3. $q(i+1) = q(i) + \nabla U(q(i))$
4. $i = i + 1$

However, this gradient-descent approach does not guarantee a solution to the problem. Gradient descent can only reach a local minimum of $U(q)$, which may not correspond to the goal state q_G , as shown in Fig. 7.9.

A planner that makes use of potential functions and attempts to avoid the issue of local minima is the *randomized potential planner* [7.59]. The idea is to combine potential functions with random walks by employing multiple planning modes. In one mode, gradient descent is applied until a local minimum is reached. Another mode uses random walks to try to escape local minima. A third mode performs backtracking whenever several attempts to escape a local minimum have failed. In many ways, this approach can be considered as a sampling-based planner. It also provides the weaker completeness guarantee but it requires parameter tuning. Recent sampling-based methods achieve better performance by spending more time exploring the space, rather than focusing heavily on a potential function.

The gradient of the potential function can be also used to define a *vector field*, which assigns a motion

for the robot at any arbitrary configuration $q \in C$. This is an important advantage of the approach, beyond its computational efficiency, since it does not only compute a single path, but also a *feedback control* strategy. This makes the approach more robust against control and sensing errors. Most of the techniques in feedback motion planning are based on the idea of *navigation functions* [7.60], which are potential functions properly constructed so as to have a single minimum. A function $\phi : C_{\text{free}} \rightarrow [0, 1]$ is called a navigation function if it:

- Is smooth (or at least C^k for $k \geq 2$),
- Has a unique minimum at q_G in the connected component of the free space that contains q_G ,
- Is uniformly maximal on the free-space boundaries,
- and is Morse, which means that all its critical points, such as saddle points, are isolated and can be avoided with small random perturbations.

Navigation functions can be constructed for sphere boundary spaces centered at q_1 that contain only spherical obstacles, as illustrated in Fig. 7.10. Then they can be extended to a large family of C-spaces that are diffeomorphic to sphere spaces, such as star-shaped spaces, as shown in Fig. 7.10. A more elaborate description of strategies for feedback motion planning will be presented in Chap. 47.

Fig. 7.9a,b Two examples of the local minimum problem with potential functions

Fig. 7.10a,b Examples of (a) sphere and (b) star spaces

Putting the issue of local minima aside, another major challenge for such potential function based approaches is constructing and representing the C-space

in the first place. This issue makes the applications of these techniques too complicated for high-dimensional problems.

7.5 Differential Constraints

Robot motions must usually conform to both global and local constraints. Global constraints on C have been considered in the form of obstacles and possibly joint limits. Local constraints are modeled with differential equations, and are therefore called *differential constraints*. These limit the velocities, and possibly accelerations, at every point due to kinematic considerations, such as wheels in contact, and dynamical considerations, such as the conservation of angular momentum.

7.5.1 Concepts and Terminology

Let $\dot{\mathbf{q}}$ denote a velocity vector. Differential constraints on C can be expressed either *implicitly* in the form $g_i(\mathbf{q}, \dot{\mathbf{q}}) = 0$ or *parametrically* in the form $\dot{\mathbf{x}} = f(\mathbf{q}, \mathbf{u})$. The implicit form is more general but often more difficult to understand and utilize. In the parametric form, a vector-valued equation indicates the velocity that is obtained for a given \mathbf{q} and \mathbf{u} , in which \mathbf{u} is an *input*, chosen from some *input space*, U . Let T denote an interval of time, starting at $t = 0$.

To model dynamics, the concepts are extended into a *phase space* X of the C-space. Usually each point $\mathbf{x} \in X$ represents both a configuration and velocity, $\mathbf{x} = (\mathbf{q}, \dot{\mathbf{q}})$. Both implicit and parametric representations are possible, yielding $g_i(\mathbf{x}, \dot{\mathbf{x}}) = 0$ and $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u})$, respectively. The latter is a common *control system* definition. Note that $\dot{\mathbf{x}} = (\dot{\mathbf{q}}, \ddot{\mathbf{q}})$, which implies that acceleration constraints and full system dynamics can be expressed.

Planning in the state space X could lead to a straightforward definition of X_{obs} by declaring $\mathbf{x} \in X_{\text{obs}}$ if and only if $\mathbf{q} \in C_{\text{obs}}$ for $\mathbf{x} = (\mathbf{q}, \dot{\mathbf{q}})$. However, another interesting possibility exists which provides some intuition about the difficulty of planning with dynamics. This possibility is based on the notion of a *region of inevitable collision*, which is defined as

$$X_{\text{ric}} = \{\mathbf{x}(0) \in X \mid \text{for any } \tilde{\mathbf{u}} \in \mathcal{U}_{\infty}, \exists t > 0 \text{ such that } \mathbf{x}(t) \in X_{\text{obs}}\}, \quad (7.4)$$

in which $\mathbf{x}(t)$ is the state at time t obtained by integrating the control function $\tilde{\mathbf{u}} : T \rightarrow U$ from $\mathbf{x}(0)$. The set \mathcal{U}_{∞} is a predefined set of all possible control functions. X_{ric} denotes the set of states in which the robot

is either in collision or, because of momentum, it cannot do anything to avoid collision. It can be considered as an invisible obstacle region that grows with speed (Fig. 7.11).

Under the general heading of *planning under differential constraints*, there are many important categories of problems that have received considerable attention in research literature. The term *nonholonomic planning* was introduced for wheeled mobile robots [7.61]. A simple example is that a car cannot move sideways, thereby making parallel parking more difficult. In general, a *nonholonomic constraint* is a differential equality constraint that cannot be integrated into a constraint that involves no derivatives. Typically, nonholonomic constraints that appear in robotics are *kinematic*, and arise from wheels in contact [7.62]. Nonholonomic constraints may also arise from dynamics.

If a planning problem involves constraints on at least velocity and acceleration, the problem is often referred to as *kinodynamic planning* [7.63]. Usually, the model expresses a *fully actuated system*, which means that it can be expressed as $\ddot{\mathbf{q}} = h(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{u})$, in which U contains an open set that includes the origin of \mathbb{R}^n (here, n is the dimension of both U and C). It is possible for a problem to be nonholonomic, kinodynamic, both, or neither; however, in recent times, the terms are not used with much precision.

Fig. 7.11 The region of inevitable collision grows quadratically with the speed

Trajectory planning is another important term, which has referred mainly to the problem of determining both a path and velocity function for a robot arm (e.g., PUMA 560). In the treatment below, all of these will be referred to as *planning under differential constraints*.

7.5.2 Discretization of Constraints

The only known methods for complete and optimal planning under differential constraints in the presence of obstacles are for the double integrator system with $X = \mathbb{R}$ [7.64] and $X = \mathbb{R}^2$ [7.65]. To develop planning algorithms in this context, several discretizations are often needed. For ordinary motion planning, only C needed to be discretized; with differential constraints, T and possibly also U require discretization, in addition to C (or X).

Discretization of the differential constraints is one of the most important issues. To solve challenging planning problems efficiently, it is often necessary to define *motion primitives* for the particular dynamical system [7.40, 66, 67]. One of the simplest ways to discretize the differential constraints is to construct a *discrete-time model*, which is characterized by three aspects:

1. The time interval T is partitioned into intervals of length Δt . This enables stages to be assigned, in which stage k indicates that $(k-1)\Delta t$ time has elapsed.
2. A finite subset U_d of the action space U is chosen. If U is already finite, then this selection may be $U_d = U$.
3. The action $\mathbf{u}(t)$ must remain constant over each time interval.

From an initial state, \mathbf{x} , a *reachability tree* can be formed by applying all sequences of discretized actions. Figure 7.12 shows the path of this tree for the *Dubins car*, which is a kinematic model of a car that drives in the plane at unit speed and cannot move in reverse. The edges of the tree are circular arcs and line segments. For general systems, each trajectory segment in the tree is determined by numerical integration of $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u})$ for a given \mathbf{u} . In general, this can be viewed as an *incremental simulator* that takes an input and produces a trajectory segment according to $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u})$.

7.5.3 Decoupled Approach

A popular paradigm for trajectory planning and other problems that involve dynamics is to decouple the problem into first planning a path and then computing a timing function along the path by performing a search in the space spanned by (s, \dot{s}) , in which s is the path

Fig. 7.12 (a) A reachability tree for the Dubins car with three actions. (b) A 2-stage tree is shown. The k -th stage produces 3^k new vertices

Fig. 7.13 An illustration of the bang-bang approach to computing a time-optimal trajectory. The solution trajectory is obtained by connecting the dots

parameter and \dot{s} is its first derivative. This leads to a diagram such as the one shown in Fig. 7.13, in which the upper region S_{obs} must be avoided because the corresponding motion of the mechanical system violates the differential constraints. Most methods are based on early work in [7.68, 69], and determine a *bang-bang control*, which means that they switch between accelerating and decelerating at full speed. This applies to determining time-optimal trajectories (optimal once constrained to the path). Dynamic programming can be used for more general problems [7.70].

For some problems and nonholonomic systems, *steering methods* have been developed to solve the two-point boundary value problem efficiently [7.62, 71]. This means that, for any pair of states, a trajectory that ignores obstacles but satisfies the differential constraints can be obtained. Moreover, for some systems,

Fig. 7.14 Reachability graph from the origin, shown after three stages (the true edges are actually parabolic arcs when acceleration or deceleration occurs). Note that a lattice is obtained, but the distance traveled in one stage increases as $|\dot{q}|$ increases

the complete set of optimal trajectories has been characterized [7.72, 73]. These control-based approaches enable straightforward adaptation of the sampling-based roadmap approach [7.74, 75]. One decoupled approach is to first plan a path that ignores differential constraints, and then incrementally transform it into one that obeys the constraints [7.62, 76].

7.5.4 Kinodynamic Planning

Due to the great difficulty of planning under differential constraints, many successful planning algorithms that address kinodynamic problems directly in the phase space X are sampling based.

Sampling-based planning algorithms proceed by exploring one or more reachability trees. Many parallels can be drawn with searching on a grid; however, reachability trees are more complicated because they do not necessarily involve a regular lattice structure. The vertex set of reachability trees is dense in most cases.

It is therefore not clear how to search a bounded region exhaustively at a fixed resolution. It is also difficult to design approaches that behave like a multiresolution grid, in which refinements can be made arbitrarily to ensure resolution completeness.

Many algorithms attempt to convert the reachability tree into a lattice. This is the basis of the original kinodynamic planning work [7.63], in which the discrete-time approximation to the double integrator, $\ddot{q} = u$, is forced onto a lattice as shown in Fig. 7.14. This enables an approximation algorithm to be developed that solves the kinodynamic planning problem in time polynomial in the approximation quality $1/\epsilon$ and the number of primitives that define the obstacles. Generalizations of the methods to fully actuated systems are described in [7.7]. Surprisingly, it is even possible to obtain a lattice for some underactuated, nonholonomic systems [7.77].

If the reachability tree does not form a lattice, then one approach is to force it to behave as a lattice by imposing a regular cell decomposition over X (or C), and allowing no more than one vertex per cell to be expanded in the reachability graph (Fig. 7.15). This idea was introduced in [7.78]. In their version of this approach, the reachability graph is expanded by dynamic programming. Each cell is initially marked as being in collision or being collision free, but not yet visited. As cells are visited during the search, they become marked as such. If a potential new vertex lands in a visited cell, it is not saved. This has the effect of pruning the reachability tree.

Other related approaches do not try to force the reachability tree onto a lattice. **RRTs** were designed to expand the tree in a way that is biased toward covering as much new territory as possible in each iteration [7.79]. Planners that are based on the concept of expansive trees attempt to control the density of ver-

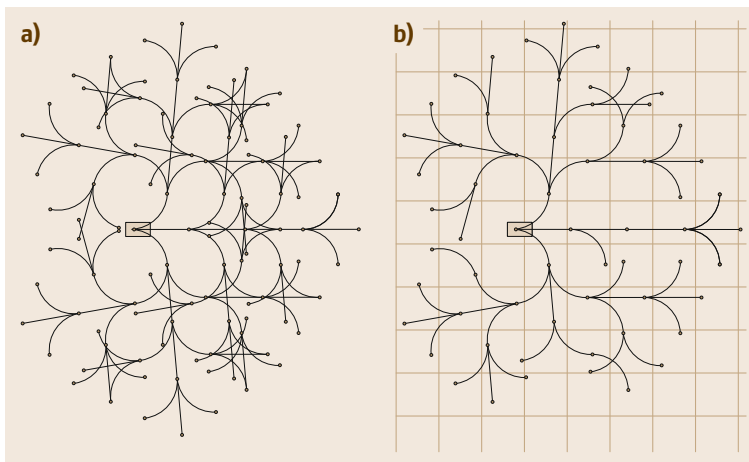

Fig. 7.15 (a) The first four stages of a dense reachability graph for the Dubins car. (b) One possible search graph, obtained by allowing at most one vertex per cell. Many branches are pruned away. In this simple example there are no cell divisions along the θ -axis

tices in the tree by analyzing neighborhoods [7.44]. The path-directed subdivision tree planner expands a tree, while building an adaptive subdivision of the state space, so as to avoid resampling the same regions of the space [7.47, 80]. Such approaches can be biased to ac-

celerate the expansion of the tree towards a goal, while still providing the weaker probabilistic completeness guarantee [7.48].  VIDEO 24 provides an example of the use of a tree-based planner together with a physics-engine which accounts for the constraints.

7.6 Extensions and Variations

A brief overview of other important extensions to the basic motion planning problem are presented in this section.

7.6.1 Closed Kinematic Chains

In many cases, the robot may consist of links that form closed loops. This arises in many important applications, for example, if two arms grasp an object then a loop is formed and a humanoid robot forms a loop if both legs touch the ground. For *parallel robots*, loops are intentionally designed into the robot [7.81]; a classic example is the Stewart–Gough platform. To model closed-chain problems, the loops are broken so that a kinematic tree of links is obtained. The main complication is that constraints on C of the form $h(q) = 0$ are introduced, which require that the loops are maintained. This causes great trouble for most planning algorithms because without loops a parameterization of C was available. The closure constraints restrict the planning to a lower-dimensional subset of C for which no parameterization is given. Computing a parameterization is generally difficult or impossible [7.82], although there has been recent progress for some special cases [7.83].

Sampling-based approaches can generally be adapted to handle closed chains. The main difficulty is that the samples $\alpha(i)$ over C are unlikely to be configurations that satisfy closure. In [7.84], both **RRTs** and **PRMs** were adapted to closed chains. **RRTs** performed much better because a costly optimization was required in the **PRM** to move samples onto the closure subspace; **RRTs** on the other hand do not require samples to lie in this subspace. By decomposing chains into active and passive links, followed by inverse kinematics computations, performance was dramatically improved for **PRMs** in [7.85]. This idea was further improved by the introduction of the *random loop generator* (**RLG**). Based on this, some of the most challenging closed-chain planning problems ever solved appear in [7.86].

7.6.2 Manipulation Planning

In most forms of motion planning, the robot is not allowed to touch obstacles. Suppose instead that it is ex-

pected to interact with its environment by manipulating objects. The goal may be to bring an object from one place to another, or to rearrange a collection of objects. This leads to a kind of hybrid motion planning problem, which mixes discrete and continuous spaces. There are discrete modes that correspond to whether the robot is carrying a part [7.87]. In the *transit mode*, the robot moves toward a part. In the *transfer mode*, it carries the part. Transitions between modes require meeting specific grasping and stability requirements. One important variant of manipulation planning is *assembly planning*, in which the goal is to fit a collection of pieces together to make an assembled product [7.88]. Most motion planning work makes limiting assumptions on the kinds of interaction that can occur between the robot and the objects. For richer models of manipulation, see [7.89].

7.6.3 Time-Varying Problems

Suppose that the workspace contains moving obstacles whose trajectories are specified as a function of time. Let $T \subset \mathbb{R}$ denote the *time interval*, which may be *bounded* or *unbounded*. A state X is defined as $X = C \times T$, in which C is the usual C -space of the robot. The obstacle region in X is characterized as

$$X_{\text{obs}} = \{(q, t) \in X \mid \mathcal{A}(q) \cap \mathcal{O}(t) \neq \emptyset\}, \quad (7.5)$$

in which $\mathcal{O}(t)$ is a time-varying obstacle. Many planning algorithms can be adapted to X , which has only one more dimension than C . The main complication is that time must always increase along a path through X .

For the easiest version of the problem, there is no bound on the robot speed. In this case, virtually any sampling-based algorithm can be adapted. Incremental searching and sampling methods apply with little modification, except that paths are directed so that forward time progress is made. Using bidirectional approaches is more difficult for time-varying problems because the goal is usually not a single point due to the time dependency. Sampling-based roadmaps can be adapted; however, a *directed roadmap* is needed, in which every edge must be directed to yield a time-monotonic path.

If the motion model is *algebraic* (i.e., expressed with polynomials) then X_{obs} is semi-algebraic. This enables cylindrical algebraic decomposition to apply. If X_{obs} is polyhedral, as depicted in Fig. 7.16, then vertical decomposition can be used. It is best to first sweep the plane along the T -axis, stopping at the critical times when the linear motion changes.

There has been no consideration so far of the speed at which the robot must move to avoid obstacles. It is obviously impractical in many applications if the solution requires the robot to move arbitrarily fast. One step towards making a realistic model is to enforce a bound on the speed of the robot. Unfortunately, the problem is considerably more difficult. Even for piecewise-linear motions of obstacles in the plane, the problem has been established to be PSPACE-hard [7.90]. A complete algorithm based on the shortest-path roadmap is presented in [7.91].

An alternative to defining the problem in $C \times T$ is to decouple it into a *path planning* part and a *motion timing* part. A collision-free path in the absence of obstacles is first computed. A search in a 2-D space is then performed to determine the *timing function* (or *time scaling*) for the path.

7.6.4 Multiple Robots

A simple extension to the basic motion planning problem can be made to handle multibody robots by including robot self-intersections; however, it is important to specify the pairs of bodies for which collision is unacceptable, for example, consecutive links in a robot arm are allowed to touch.

Fig. 7.16 A time-varying example with linear obstacle motion

Substantial attention has been devoted to the problem of planning for multiple robots (VIDEO 21 and VIDEO 22). Suppose there are m robots. A state space is defined that considers the configurations of all robots simultaneously,

$$X = C^1 \times C^2 \times \cdots \times C^m. \quad (7.6)$$

A state $\mathbf{x} \in X$ specifies all robot configurations, and may be expressed as $\mathbf{x} = (q^1, q^2, \dots, q^m)$. The dimension of X is N , which is $N = \sum_{i=1}^m \dim(C^i)$.

There are two sources of obstacle regions in the state space: (1) *robot-obstacle* collisions, and (2) *robot-robot* collisions. For each i such that $1 \leq i \leq m$, the subset of X that corresponds to robot \mathcal{A}^i in collision with the obstacle region \mathcal{O} is

$$X_{\text{obs}}^i = \{\mathbf{x} \in X \mid \mathcal{A}^i(q^i) \cap \mathcal{O} \neq \emptyset\}. \quad (7.7)$$

This models the robot-obstacle collisions.

For each pair, \mathcal{A}^i and \mathcal{A}^j , of robots, the subset of X that corresponds to \mathcal{A}^i in collision with \mathcal{A}^j is

$$X_{\text{obs}}^{ij} = \{\mathbf{x} \in X \mid \mathcal{A}^i(q^i) \cap \mathcal{A}^j(q^j) \neq \emptyset\}. \quad (7.8)$$

Both (7.7) and (7.8) will be combined in (7.9) to yield X_{obs} . The obstacle region in X is

$$X_{\text{obs}} = \left(\bigcup_{i=1}^m X_{\text{obs}}^i \right) \cup \left(\bigcup_{ij, i \neq j} X_{\text{obs}}^{ij} \right). \quad (7.9)$$

Once these definitions have been made, any general-purpose planning algorithm can be applied because X and X_{obs} appear no different from C and C_{obs} , except that the dimension N may be very high. Approaches that plan directly in X are called *centralized*. The high dimensionality of X motivates the development of *decoupled* approaches that handle some aspects of the planning independently for each robot. Decoupled approaches are usually more efficient, but this usually comes at the expense of sacrificing completeness. An early decoupled approach is *prioritized planning* [7.92, 93], in which a path and timing function is computed for the i -th robot while treating the first $i-1$ robots as moving obstacles as they follow their paths. Another decoupled approach is *fixed-path* coordination [7.94], in which the paths are planned independently for each robot, and then their timing functions are determined by computing a collision-free path through an m -dimensional *coordination space*. Each axis in this space corresponds to the domain of the path of one robot. Fig. 7.17 shows an example. The idea has been generalized to coordination on roadmaps [7.95, 96].

7.6.5 Uncertainty in Predictability

If the execution of the plan is not predictable, then feedback is needed. The uncertainty may be modeled either *implicitly*, which means that the plan is able to respond to unexpected future configurations, or *explicitly*, which means that the uncertainty is precisely characterized and analyzed in the development of a plan. Potential-function-based approaches are one way of achieving feedback motion planning.

A plan can be represented as a vector field over C_{free} , in which each vector indicates the required velocity. The integral curves of the field should flow into the goal without leaving C_{obs} . If dynamics are a concern, then the vector field can be tracked by an *acceleration-based control model*

$$\mathbf{u} = K(f(\mathbf{q}) - \dot{\mathbf{q}}) + \nabla_{\dot{\mathbf{q}}} f(\mathbf{q}), \quad (7.10)$$

in which K is a scalar *gain constant*. Alternatively, a vector field may be designed directly on the phase space, X ; however, there are not methods to compute such fields efficiently under general conditions. This can also be considered as a feedback control problem with implicit, nonlinear constraints on X .

If the uncertainty is modeled explicitly, then a *game against nature* is obtained, in which the uncertainty is caused by a special decision maker called *nature*. The decisions of nature can either be modeled *nondeterministically*, which means that a set of possible actions is specified, or *probabilistically*, which means that a probability distribution or density is specified over the nature actions. Under nondeterministic uncertainty, *worst-case analysis* is usually performed to select a plan; under probabilistic uncertainty, *expected-case analysis* is usually performed. Numerous approaches exist for such problems, including value iteration, Dijkstra-like algorithms, and reinforcement learning algorithms [7.7].

7.6.6 Sensing Uncertainty

Consider solving tasks such as localization, map building, manipulation, target tracking, and pursuit-evasion (hide-and-seek) with limited sensing. If the current configuration or state is not known during execution, then the problem may appear quite different. Information is obtained from sensors, and the planning problem naturally lives in an *information space* or *I-space* [7.7, Chap. 11]. The state may include the configuration, velocities, or even the map of the environment (e.g., obstacles). The most basic I-space is the set of all histories that can be obtained during execution, based on all sensing observations, actions previously applied,

Fig. 7.17 The obstacles that arise from coordinating m robots are always cylindrical. The set of all $\frac{1}{2}m(m-1)$ axis-aligned 2-D projections completely characterizes X_{obs}

and the initial conditions. The goal in developing efficient algorithms in this context is to determine information mappings that reduce the I-space size or complexity so that plans that can be computed that use *information feedback*. The traditional way to use the information state is for estimating the state. This is sufficient for solving many tasks, but it is often not necessary. It may be possible to design and execute successful plans without ever knowing the current state. This can lead to more robust robot systems which may also be cheaper to manufacture due to weaker sensing requirements.

Two important families of I-spaces are *nondeterministic* and *probabilistic*. A nondeterministic information state (I-state) is a set of states that are possible given the available history of sensor observations and actions applied during execution. The nondeterministic I-space is the set of all possibilities. Similarly, a probabilistic I-state is a probability density function over the state space, conditioned on the available history. The probabilistic I-space is often called the *belief space*, which represents the set of all probability density functions. Both filtering and planning over these spaces remains a topic of active research. One of most useful and classical results is the *Kalman filter* [7.97], for which the belief space reduces to Gaussians, allowing it to be completely parametrized by mean and covariance of state. Many approaches to reasoning in these I-spaces attempt to reduce its complexity, through combinatorial reasoning in the case of nondeterministic I-spaces [7.98] and through approximations,

sampling, and dimensionality reduction techniques in belief spaces [7.99–103]. For example, a sampling-based roadmap can be constructed directly in the belief space [7.104].

7.6.7 Optimal Planning

In most formulations of planning, computing an optimal solution is given little or no importance. Several factors have contributed to this trend. One of the most fundamental is that a natural criterion of optimality often does not exist. Unlike control theory, where optimality is a central goal, the main task in planning is to avoid obstacles. Imagine walking quickly through a furniture store. Moving along the shortest possible path would cause you to touch the corners of obstacles, which might not be desirable. You could try to maximize clearance, but this causes longer paths, which again might not be desirable. Another factor is that solutions produced by path planning algorithms tend to not be excessively long, especially after some quick post-processing in the case of sampling-based planners. Finally, the computational complexity of the optimal planning problem is typically worse than its feasible (not necessarily optimal) counterpart. One of the most notable exceptions is planning in field robotics (outdoor vehicles in unstructured terrain), for which cost func-

tion determines navigability at each point, leading to the well-known family of *D* algorithms* [7.105, 106].

In spite of these issues, several useful approaches and interesting ideas have emerged. As mentioned in Sect. 7.4.1, the shortest-path roadmap is an effective multiple-query approach in the case of a 2-D, polygonal C-space. Alternatively, the *continuous Dijkstra* method provides an effective single-query approach by propagating wavefronts that correspond to level sets of the optimal cost from the initial configuration [7.107, 108]. The wavefronts are propagated combinatorially, stopping only at critical events, leading to an exact, optimal solution. In the case of 3-D polyhedral C-spaces, the shortest path problem already becomes PSPACE-hard [7.15]. However, algorithms that produce approximately optimal solutions exist [7.109–111], and are useful in C-spaces of several dimensions. Dijkstra-like approaches can be adapted to include various forms of uncertainty and differential constraints, and are all derived in some way from *value iteration* methods introduced by Bellman in the 1950s. See Chaps. 7, 10, and 14 of [7.7] for more discussion. Pushing into even higher dimensions, recent sampling-based planning methods have produced asymptotically optimal versions *RRTs* [7.112] and *PRMs* [7.112, 113], which have been shown to produce paths that improve in quality as time progresses.

7.7 Advanced Issues

We cover here a series of more advanced issues, such as topics from topology and sampling theory, and how they influence the performance of motion planners. The last section is devoted to computational algebraic geometry techniques that achieve completeness in the general case. Rather than being a practical alternative, these techniques serve as an upper bound on the best asymptotic running time that could be obtained.

7.7.1 Topology of Configuration Spaces

Manifolds

One reason that the topology of a C-space is important is because it affects its representation. Another reason is that, if a path-planning algorithm can solve problems in a topological space, then that algorithm may carry over to topologically equivalent spaces.

The following definitions are important in order to describe the topology of C-space. A map $\phi : S \rightarrow T$ is called a *homeomorphism* if ϕ is a bijection and both ϕ and ϕ^{-1} are continuous. When such a map exists, S and T are said to be homeomorphic. A set S is an n -dimensional *manifold* if it is locally homeomorphic

to \mathbb{R}^n , meaning that each point in S possesses a neighborhood that is homeomorphic to \mathbb{R}^n . For more details, see [7.114, 115].

In the vast majority of motion planning problems, the configuration space is a manifold. An example of a C-space that is not a manifold is the closed unit square: $[0, 1] \times [0, 1] \subset \mathbb{R}^2$, which is a manifold with boundary obtained by pasting the one-dimensional boundary on the two-dimensional open set $(0, 1) \times (0, 1)$. When a C-space is a manifold, then we can represent it with just n parameters, in which n is the dimension of the configuration space. Although an n -dimensional manifold can be represented using as few as n parameters, due to constraints it might be easier to use a representation that has higher number of parameters, e.g., the unit circle \mathbb{S}^1 can be represented as $\mathbb{S}^1 = \{(x, y) | x^2 + y^2 = 1\}$ by embedding \mathbb{S}^1 in \mathbb{R}^2 . Similarly, the torus T^2 can be embedded in \mathbb{R}^3 .

Representation

Embeddings into higher-dimensional spaces can facilitate many C-space operations. For example, the orientation of a rigid body in space can be represented by

a $n \times n$ matrix of real numbers. The n^2 matrix entries must satisfy a number of smooth equality constraints, making the manifold of such matrices a *submanifold* of \mathbb{R}^{m^2} . One advantage is that these matrices can be multiplied to get another matrix in the manifold. For example, the orientation of a rigid-body in n -dimensional space ($n = 2$ or 3) is described by the set $SO(n)$, the set of all $n \times n$ rotation matrices. The position and orientation of a rigid body is represented by the set $SE(n)$, the set of all $n \times n$ homogeneous transformation matrices. These matrix groups can be used to (1) represent rigid-body configurations, (2) change the reference frame for the representation of a configuration, and (3) displace a configuration.

There are numerous parameterizations of $SO(3)$ [7.116] but unit quaternions correctly preserve the C -space topology as S^1 represents 2-D rotations. Quaternions were introduced in Chap. 2. There is, however, a two-to-one correspondence between unit quaternions and 3-D rotation matrices. This causes a topological issue that is similar to the equivalence of 0 and 2π for 2-D rotations. One way to account for this is to declare antipodal (opposite) points on S^3 to be equivalent. In planning, only the upper hemisphere of S^3 is needed, and paths that cross the equator instantly reappear on the opposite side of S^3 , heading back into the northern hemisphere. In topology, this is called a real projective space: \mathbb{RP}^3 . Hence, the C -space of a 3-D body capable only of rotation is \mathbb{RP}^3 . If both translation and rotation are allowed, then $SE(3)$, the set of all 4×4 homogeneous transformation matrices, yields

$$C = \mathbb{R}^3 \times \mathbb{RP}^3, \quad (7.11)$$

which is six dimensional. A configuration $q \in C$ can be expressed using quaternions with seven coordinates, (x, y, z, a, b, c, d) , in which $a^2 + b^2 + c^2 + d^2 = 1$. More examples can be found in Table 7.1.

7.7.2 Sampling Theory

Since the most successful paradigm for motion planning today is the sampling-based framework, presented

Table 7.1 Some common robots and their C -spaces

Type of robot	C -space representation
Mobile robot translating in the plane	\mathbb{R}^2
Mobile robot translating and rotating in the plane	$SE(2)$ or $\mathbb{R}^2 \times S^1$
Rigid body translating in the three-space	\mathbb{R}^3
A spacecraft	$SE(3)$ or $\mathbb{R}^3 \times SO(3)$
An n -joint revolute arm	T^n
A planar mobile robot with an attached n -joint arm	$SE(2) \times T^n$

in Sect. 7.3, sampling theory becomes relevant to the motion planning problem.

Metrics in Configuration/State Spaces

Virtually all sampling-based methods require some notion of distance on C . For example, the sampling-based roadmap method selects candidate vertices to connect a new configuration given a distance-defined neighborhood. Similarly, the rapidly exploring dense trees expands the tree from the nearest node of the tree to a newly sampled configuration. Usually, a *metric*, $\rho : C \times C \rightarrow \mathbb{R}$, is defined, which satisfies the standard axioms: nonnegativity, reflexivity, symmetry, and the triangle inequality.

Two difficult issues that arise in constructing a metric are: (1) the topology of C must be respected, and (2) several different quantities, such as linear and angular displacements, must be compared in some way. To illustrate the second issue, consider defining a metric ρ_z for a space constructed as $Z = X \times Y$ as

$$\begin{aligned} \rho_z(z, z') &= \rho_z(x, y, x', y') \\ &= c_1 \rho_x(x, x') + c_2 \rho_y(y, y'). \end{aligned} \quad (7.12)$$

Above, c_1 and c_2 are arbitrary positive constants that indicate the relative weights of the two components. For a 2-D rotation, θ_i , expressed as $a_i = \cos \theta_i$ and $b_i = \sin \theta_i$, a useful metric is

$$\rho(a_1, b_1, a_2, b_2) = \cos^{-1}(a_1 a_2 + b_1 b_2). \quad (7.13)$$

The 3-D equivalent is obtained by defining

$$\rho_0(h_1, h_2) = \cos^{-1}(a_1 a_2 + b_1 b_2 + c_1 c_2 + d_1 d_2), \quad (7.14)$$

in which each $h_i = (a_i, b_i, c_i, d_i)$ is a unit quaternion. The metric is defined as $\rho(h_1, h_2) = \min(\rho_0(h_1, h_2), \rho_0(h_1, -h_2))$, by respecting the required identification of antipodal points. This computes the shortest distance in \mathbb{R}^4 , for a path constrained to the unit sphere.

In some algorithms, defining volume on C may also be important. In general, this leads to a *measure space*, for which the volume function (called the *measure*) must satisfy axioms that resemble the probability axioms, but without normalization. For transformation groups, one must be careful to define volumes in a way that is invariant with respect to transformations. Such volumes are called *Haar measures*. Defining volumes via balls using the metric definitions (7.13) and (7.14) actually satisfy this concern.

Probabilistic Versus Deterministic Sampling

The C -space may be sampled *probabilistically* or *deterministically*. Either way, the requirement is usually that a dense sequence α of samples is obtained.

This means that, in the limit as the number of samples tends to infinity, the samples become arbitrarily close to every point in C . For probabilistic sampling, this denseness (with probability one) ensures *probabilistic completeness* of a planning algorithm. For deterministic sampling, it ensures *resolution completeness*, which means that, if a solution exists, the algorithm is guaranteed to find it; otherwise, it may run forever.

For probabilistic sampling, samples are selected randomly over C , using a uniform probability density function. To obtain uniformity in a meaningful way, the Haar measure should be used. This is straightforward in many cases; $SO(3)$ however is tricky. A uniform (with respect to Haar measure) random quaternion is selected as follows. Choose three points $u_1, u_2, u_3 \in [0, 1]$ uniformly at random, and let [7.117]

$$\mathbf{h} = \left(\sqrt{1-u_1} \sin 2\pi u_2, \sqrt{1-u_1} \cos 2\pi u_2, \right. \\ \left. \sqrt{u_1} \sin 2\pi u_3, \sqrt{u_1} \cos 2\pi u_3 \right). \quad (7.15)$$

Even though random samples are uniform in some sense, they are also required to have some irregularity to satisfy statistical tests. This has motivated the development of deterministic sampling schemes that offer better performance [7.118]. Instead of being concerned with randomness, deterministic sampling techniques are designed to optimize criteria, such as *discrepancy* and *dispersion*. Discrepancy penalizes regularity in the sample, which frequently causes trouble in numerical integration. Dispersion gives the radius of the largest empty (not containing samples) ball. Thus, driving dispersion down quickly means that the whole space is explored quickly. Deterministic samples may be *irregular* neighborhood structure (appearing much like random samples), or *regular* neighborhood structure, which means that points are arranged along a grid or lattice. For more details in the context of motion planning, see [7.7].

7.7.3 Computational Algebraic Geometry Techniques

Sampling-based algorithms provide good practical performance at the expense of achieving only a weaker form of completeness. On the other hand, complete algorithms, which are the focus of this section, are able to deduce that there is no solution to a planning problem.

Complete algorithms are able to solve virtually any motion planning problem as long as C_{obs} is represented by patches of algebraic surfaces. Formally, the model must be *semi-algebraic*, which means that it is formed

from unions and intersections of roots of multivariate polynomials in q , and for computability, the polynomials must have rational coefficients (otherwise roots may not have finite representations). The set of all roots to polynomials with rational coefficients is called *real algebraic numbers* and has many nice computational properties. See [7.12, 119–121] for more information on the exact representation and calculation with real algebraic numbers. For a gentle introduction to algebraic geometry, see [7.82].

To use techniques based on algebraic geometry, the first step is to convert the models into the required polynomials. Suppose that the models, the robot, \mathcal{A} , and the obstacles \mathcal{O} are semi-algebraic (this includes polyhedral models). For any number of attached 2-D or 3-D bodies, the kinematic transformations can be expressed using polynomials. Since polynomial transformations of polynomials yield polynomials, the transformed robot model is polynomial. The algebraic surfaces that comprise C_{obs} are computed by carefully considering all contact types, which characterize all ways to pair a robot feature (faces, edges, vertices) with an obstacle feature [7.6, 7, 9, 122]. This step already produces too many model primitives to be useful in most applications.

Once the semi-algebraic representation has been obtained, powerful techniques from algebraic geometry can be exploited. One of the most widely known algorithms, *cylindrical algebraic decomposition* [7.119, 123, 124], provides the information needed to solve the motion planning problem. It was originally designed to determine whether *Tarski sentences*, which involve quantifiers and polynomials, are satisfiable, and to find an equivalent expression that does not involve quantifiers. The decomposition produces a finite set of cells over which the signs of the polynomials remain fixed. This enables a systematic approach to satisfiability and quantifier elimination. It was recognized by *Schwartz* and *Sharir* [7.121] that it also solves motion planning.

The method is conceptually simple, but there are many difficult technical details. The decomposition is called cylindrical because the cells are organized into vertical columns of cells, see Fig. 7.18 for a 2-D example. There are two kinds of critical events, shown in Fig. 7.19. At critical points, rays are extended indefinitely in both vertical directions. The decomposition differs from the vertical decomposition in Fig. 7.7 because there the rays were only extended until the next obstacle was hit. Here, columns of cells are obtained.

In n dimensions, each column represents a chain of cells. The first and last cells are n -dimensional and unbounded. The remaining cells are bounded and alternate between being $(n-1)$ -dimensional and n -dimensional.

The bounded n -dimensional cells are bounded above and below by the roots of single multivariate polynomials. This makes it simple to describe the cells and their connectivity. To compute this cell decomposition, the algorithm constructs a cascading chain of projections. In the first step, C_{obs} is projected from \mathbb{R}^n to \mathbb{R}^{n-1} . This is followed by a projection into \mathbb{R}^{n-2} . This repeats until \mathbb{R} is obtained with a univariate polynomial that encodes the places at which all critical boundaries need to be placed. In a second phase of the algorithm, a series of liftings is performed. Each lifting takes the polynomials and cell decomposition over \mathbb{R}^i and lifts them via columns of cells to \mathbb{R}^{i+1} . A single lifting is illustrated in Fig. 7.18b. The running time of the full algorithm depends on the particular methods used to perform the algebraic computations. The total running time required to use cylindrical algebraic decomposition for motion planning is bounded by $(md)^{O(1)^n}$, in which m is the number of polynomials to describe C_{obs} (a huge number), and d is the maximum algebraic degree. (It may seem odd for $O(\cdot)$ to appear in the middle of an expression. In this context, it means that there exists some $c \in [0, \infty)$ such that the running time is bounded by $(md)^{c^n}$. Note that another O is not necessary in the front of the whole formula.) The main point to remember is that the algorithm is doubly exponential in the dimension of C (even the number of cells is doubly exponential).

Although performing the cylindrical decomposition is sufficient for solving motion planning, it computes more information than is necessary. This motivates Canny's roadmap algorithm [7.12], which produces a roadmap directly from the semi-algebraic set, rather than constructing a cell decomposition along the way. Since there are doubly exponentially many cells in the cylindrical algebraic decomposition, avoiding this construction pays off. The resulting roadmap method of Canny solves the motion planning problem in time that is again polynomial in the number of polynomials and polynomial in the algebraic degree, but is only singly exponential in dimension [7.12].

The basic idea is to find silhouette curves in \mathbb{R}^2 of C_{obs} in \mathbb{R}^n . The method finds zero-dimensional critical points and one-dimensional critical curves. The critical curves become roadmap edges, and the criti-

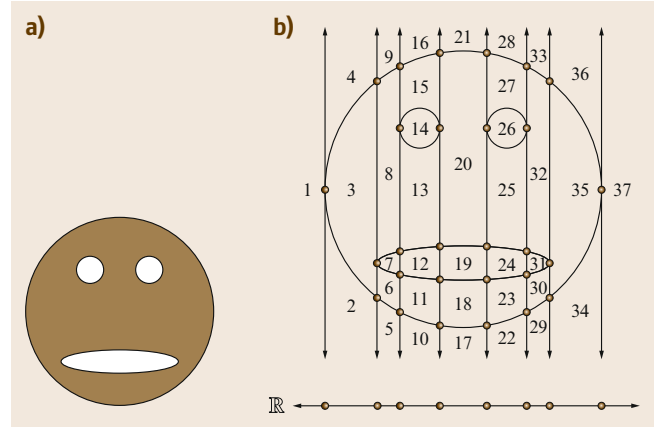

Fig. 7.18 (a) A face modeled with four algebraic primitives, and (b) a cylindrical algebraic decomposition of the face

Fig. 7.19 Critical points occur either when the surface folds over in the vertical direction or when surfaces intersect

cal points are places at which the algorithm recursively finds silhouettes of $(n-1)$ -dimensional slices of C_{obs} . These contribute more critical points and curves. The curves are added to the roadmap, and the algorithm recurses again on the critical points. The recursive iterations terminate at $n=2$. Canny showed that the resulting union of critical curves preserves the connectivity of C_{obs} (and hence, C_{free}). Some of the technical issues are: the algorithm works with a stratification of C_{obs} into manifolds; there are strong general position assumptions that are hard to meet; paths are actually considered along the boundary of C_{free} ; and the method does not produce a parameterized solution path. For improvements to Canny's algorithm and many other important details, see [7.119].

7.8 Conclusions and Further Reading

The brief survey given here hardly does justice to motion planning, which is a rich and active research field. For more details, we recommend consulting two recent textbooks [7.5, 7]. In addition, see the classic textbook

of Latombe [7.6], the classic papers in [7.4], and the recent surveys in [7.2, 3]. Furthermore, consult the related handbook chapters that were indicated throughout this chapter.

8. Motion Control

Wan Kyun Chung, Li-Chen Fu, Torsten Kröger

This chapter will focus on the motion control of robotic rigid manipulators. In other words, this chapter does not treat the motion control of mobile robots, flexible manipulators, and manipulators with elastic joints. The main challenge in the motion control problem of rigid manipulators is the complexity of their dynamics and uncertainties. The former results from nonlinearity and coupling in the robot manipulators. The latter is twofold: structured and unstructured. Structured uncertainty means imprecise knowledge of the dynamic parameters and will be touched upon in this chapter, whereas unstructured uncertainty results from joint and link flexibility, actuator dynamics, friction, sensor noise, and unknown environment dynamics, and will be treated in other chapters.

In this chapter, we begin with an introduction to motion control of robot manipulators from a fundamental viewpoint, followed by a survey and brief review of the relevant advanced materials. Specifically, the dynamic model and useful properties of robot manipulators are recalled in Sect. 8.1. The joint and operational space control approaches, two different viewpoints on control of robot manipulators, are compared in Sect. 8.2. Independent joint control and proportional–integral–derivative (PID) control, widely adopted in the field of industrial robots, are presented in Sects. 8.3 and 8.4, respectively. Tracking control, based on feedback linearization, is introduced in Sect. 8.5. The computed–torque control and its variants are described in Sect. 8.6. Adaptive control is introduced in Sect. 8.7 to solve the problem of structural uncertainty, whereas the optimality and robustness issues are covered in Sect. 8.8. To compute suitable set point signals as input values for these motion controllers, Sect. 8.9 introduces reference trajectory planning concepts. Since most controllers of robot manipulators are implemented

by using microprocessors, the issues of digital implementation are discussed in Sect. 8.10. Finally, learning control, one popular approach to intelligent control, is illustrated in Sect. 8.11.

8.1	Introduction to Motion Control	164
8.1.1	Dynamical Model	164
8.1.2	Control Tasks	165
8.1.3	Summary	165
8.2	Joint Space Versus Operational Space Control	166
8.2.1	Joint Space Control	166
8.2.2	Operational Space Control	166
8.3	Independent-Joint Control	167
8.3.1	Controller Design Based on the Single-Joint Model	167
8.3.2	Controller Design Based on the Multijoint Model	169
8.3.3	Summary	169
8.4	PID Control	169
8.4.1	PD Control for Regulation	169
8.4.2	PID Control for Regulation	170

8.1 Introduction to Motion Control

The dynamical model of robot manipulators will be recalled in this section. Furthermore, important properties of this dynamical model, which is useful in controller design, will then be addressed. Finally, different control tasks of the robot manipulators will be defined.

8.1.1 Dynamical Model

For motion control, the dynamical model of rigid robot manipulators is conveniently described by Lagrange dynamics. Let the robot manipulator have n links and let the $(n \times 1)$ -vector \mathbf{q} of joint variables be $\mathbf{q} = [q_1, \dots, q_n]^T$. The dynamic model of the robot manipulator is then described by Lagrange's equation [8.1–6]

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}) = \boldsymbol{\tau}, \quad (8.1)$$

where $\mathbf{H}(\mathbf{q})$ is the $(n \times n)$ inertia matrix, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}$ is the $(n \times 1)$ -vector of Coriolis and centrifugal forces, $\boldsymbol{\tau}_g(\mathbf{q})$ is the $(n \times 1)$ -vector of gravity force, and $\boldsymbol{\tau}$ is the $(n \times 1)$ -vector of joint control inputs to be designed. Friction and disturbance input have been neglected here.

Remark 8.1

Other contributions to the dynamic description of the robot manipulators may include the dynamics of the actuators, joint and link flexibility, friction, noise, and disturbances. Without loss of generality, the case of the rigid robot manipulators is stressed here.

The control schemes that we will introduce in this chapter are based on some important properties of the dynamical model of robot manipulators. Before giving a detailed introduction to these different schemes, let us first give a list of those properties.

Property 8.1

The inertia matrix is a symmetric positive-definite matrix, which can be expressed

$$\lambda_h \mathbf{I}_n \leq \mathbf{H}(\mathbf{q}) \leq \lambda_H \mathbf{I}_n, \quad (8.2)$$

where λ_h and λ_H denote positive constants.

Property 8.2

The matrix $\mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) = \dot{\mathbf{H}}(\mathbf{q}) - 2\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ is skew-symmetric for a particular choice of $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ (which is always possible), i. e.,

$$\mathbf{z}^T \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) \mathbf{z} = 0 \quad (8.3)$$

for any $(n \times 1)$ -vector \mathbf{z} .

Property 8.3

The $(n \times n)$ -matrix $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ satisfies

$$\|\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\| \leq c_o \|\dot{\mathbf{q}}\| \quad (8.4)$$

for some bounded constant c_o .

Property 8.4

The gravity force/torque vector satisfies

$$\|\boldsymbol{\tau}_g(\mathbf{q})\| \leq g_o \quad (8.5)$$

for some bounded constant g_o .

Property 8.5

The equation of motion is linear in the inertia parameters. In other words, there is a $(r \times 1)$ constant

vector \mathbf{a} and an $(n \times r)$ regressor matrix $\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ such that

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}) = \mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})\mathbf{a}. \quad (8.6)$$

The vector \mathbf{a} is comprised of link masses, moments of inertia, and the link, in various combinations.

Property 8.6

The mapping $\boldsymbol{\tau} \rightarrow \dot{\mathbf{q}}$ is passive; i. e., there exists $\alpha \geq 0$ such that

$$\int_0^t \dot{\mathbf{q}}^T(\beta) \boldsymbol{\tau}(\beta) d\beta \geq -\alpha, \quad \forall t < \infty. \quad (8.7)$$

Remarks 8.1

- Properties 8.3 and 8.4 are very useful since they allow us to establish upper bounds on the nonlinear terms in the dynamical model. As we will see further, several control schemes require knowledge of such upper bounds.
- In Property 8.5, the parameter vector \mathbf{a} is comprised of several variables in various combinations. The dimensionality of the parameter space is not unique, and the search over the parameter space is an important problem.
- In this section, we assume that *the robot manipulator is fully actuated* and this indicates that there is an independent control input for each degree of freedom (DOF). In contrast, the robot manipulators with joint or link flexibility are no longer fully actuated and the control problems are more difficult in general.

8.1.2 Control Tasks

It is instructive for comparative purposes to classify control objectives into the following two classes:

- *Trajectory tracking* is aimed at following a time-varying joint reference trajectory specified within

the manipulator workspace. In general, this desired trajectory is assumed to comply with the actuators' capacity. In other words, the joint velocity and acceleration associated with the desired trajectory should not violate, respectively, the velocity and acceleration limit of the manipulator. In practice, the capacity of actuators is set by torque limits, which result in bounds on the acceleration that are complex and state dependent.

- *Regulation* sometimes is also called point-to-point control. A fixed configuration in the joint space is specified; the objective is to bring to and keep the joint variable at the desired position in spite of torque disturbances and independently of the initial conditions. The behavior of transients and overshooting, are in general, not guaranteed.

The selection of the controller may depend on the type of task to be performed. For example, tasks only requiring the manipulator to move from one position to another without requiring significant precision during the motion between these two points can be solved by regulators, whereas such as welding, painting, and so on, require tracking controllers.

Remarks 8.2

- The regulation problem may be seen as a special case of the tracking problem (for which the desired joint velocity and acceleration are zero).
- The task specification above is given in the joint space and results in joint space control, which is the main content of this chapter. Sometimes, the task specification of the robot manipulators in terms of the desired trajectory of the end-effector (e.g., control with eye-in-hand) is carried out in the task space and gives rise to the operational space control, which will be introduced in Sect. 8.2.

8.1.3 Summary

In this section, we introduced the dynamical model of the robot manipulators and important properties of this dynamical model. Finally, we defined different control tasks of the robot manipulators.

8.2 Joint Space Versus Operational Space Control

In a motion control problem, the manipulator moves to a position to pick up an object, transports that object to another location, and deposits it. Such a task is an integral part of any higher-level manipulation tasks such as painting or spot-welding.

Tasks are usually specified in the task space in terms of a desired trajectory of the end-effector, while control actions are performed in the joint space to achieve the desired goals. This fact naturally leads to two kinds of general control methods, namely *joint space control* and *operational space control (task space control)* schemes.

8.2.1 Joint Space Control

The main goal of the joint space control is to design a feedback controller such that the joint coordinates $q(t) \in R^n$ track the desired motion $q_d(t)$ as closely as possible. To this end, consider the equations of motion (8.1) of an n -DOF manipulator expressed in the joint space [8.2, 4]. In this case, the control of robot manipulators is naturally achieved in the joint space, since the control inputs are the joint torques. Nevertheless, the user specifies a motion in terms of end-effector coordinates, and thus it is necessary to understand the following strategy.

Figure 8.1 shows the basic outline of the joint space control methods. Firstly, the desired motion, which is described in terms of end-effector coordinates, is converted to a corresponding joint trajectory using the inverse kinematics of the manipulator. Then the feedback controller determines the joint torque necessary to move the manipulator along the desired trajectory specified in joint coordinates starting from measurements of the current joint states [8.1, 4, 7, 8].

Since it is always assumed that the desired task is given in terms of the time sequence of the joint motion, joint space control schemes are quite adequate in situations where manipulator tasks can be accurately preplanned and little or no online trajectory adjustments are necessary [8.1, 4, 7, 9]. Typically, inverse kinematics is performed for some intermediate task points, and the joint trajectory is interpolated using the intermediate joint solutions. Although the command trajectory consists of straight-line motions in end-effector coordinates

between interpolation points, the resulting joint motion consists of curvilinear segments that match the desired end-effector trajectory at the interpolation points.

In fact, the joint space control includes simple proportional-derivative (PD) control, PID control, inverse dynamic control, Lyapunov-based control, and passivity-based control, as explained in the following sections.

8.2.2 Operational Space Control

In more complicated and less certain environments, end-effector motion may be subject to online modifications in order to accommodate unexpected events or to respond to sensor inputs. There are a variety of tasks in manufacturing where these type of control problem arise. In particular, it is essential when controlling the interaction between the manipulator and environment is of concern.

Since the desired task is often specified in the operational space and requires precise control of the end-effector motion, joint space control schemes are not suitable in these situations. This motivated a different approach, which can develop control schemes directly based on the dynamics expressed in the operational space [8.10, 11].

Let us suppose that the Jacobian matrix, denoted by $J(q) \in R^{n \times n}$, transforms the joint velocity ($\dot{q} \in R^n$) to the task velocity ($\dot{x} \in R^n$) according to

$$\dot{x} = J(q)\dot{q}. \quad (8.8)$$

Furthermore, assume that it is invertible. Then, the operational space dynamics is expressed as follows

$$f_c = \Lambda(q)\ddot{x} + \Gamma(q, \dot{q})\dot{x} + \eta(q), \quad (8.9)$$

where $f_c \in R^n$ denotes the command forces in the operational space; the *pseudo-inertia matrix* is defined by

$$\Lambda(q) = J^{-T}(q)H(q)J^{-1}(q), \quad (8.10)$$

and $\Gamma(q, \dot{q})$ and $\eta(q)$ are given by

$$\begin{aligned} \Gamma(q, \dot{q}) &= J^{-T}(q)C(q, \dot{q})J^{-1}(q) \\ &\quad - \Lambda(q)J(q)J^{-1}(q), \\ \eta(q) &= J^{-T}(q)\tau_g(q). \end{aligned}$$

The task space variables are usually reconstructed from the joint space variables, via the kinematic mappings. In fact, it is quite rare to have sensors to directly measure end-effector positions and velocities. Also, it

Fig. 8.1 Generic concept of joint space control

is worth remarking that an analytical Jacobian is utilized since the control schemes operate directly on task space quantities, i. e., the end-effector position and orientation.

The main goal of the operational space control is to design a feedback controller that allows execution of an end-effector motion $x(t) \in R^n$ that tracks the desired end-effector motion $x_d(t)$ as closely as possible. To this end, consider the equations of motion (8.9) of the manipulator expressed in the operational space. For this case, Fig. 8.2 shows a schematic diagram of the operational space control methods. There are several advantages to such an approach because operational

Fig. 8.2 Basic concept of operational space control

space controllers employ a feedback loop that directly minimizes task errors. Inverse kinematics need not be calculated explicitly, since the control algorithm embeds the velocity-level forward kinematics (8.8), as shown in the figure. Now, motion between points can be a straight-line segment in the task space.

8.3 Independent-Joint Control

By independent-joint control (i. e., decentralized control), we mean that the control inputs of each joint only depends on the measurement of the corresponding joint displacement and velocity. Due to its simple structure, this kind of control schemes offers many advantages. For example, by using independent-joint control, communication among different joints is saved. Moreover, since the computational load of controllers may be reduced, only low-cost hardware is required in actual implementations. Finally, independent-joint control has the feature of scalability, since the controllers on all the joints have the same formulation. In this section, two kinds of design of independent-joint control will be introduced: one focused on the dynamical model of each joint (i. e., based on the single-joint model) and the other based on the analysis of the overall dynamical model (i. e., the multijoint model) of robot manipulators.

8.3.1 Controller Design Based on the Single-Joint Model

The simplest independent-joint control strategy is to control each joint axis as a single-input single-output (SISO) system. Coupling effects among joints due to varying configuration during motion are treated as disturbance inputs. Without loss of generality, the actuator is taken as a rotary electric direct-current (DC) motor. Hence, the block diagram of the control scheme of joint i can be represented in the domain of the complex variables as shown in Fig. 8.3. In this scheme, θ is the angular variable of the motor, J is the effective inertia viewed from the motor side, R_a is the armature resistance (auto-inductance being neglected), and k_t and k_v are, respectively, the torque and motor constants. Furthermore, G_v denotes the voltage gain of the power

amplifier so that the reference input is the input voltage V_c of the amplifier instead of the armature voltage V_a . It has also been assumed that $F_m \ll k_v k_t / R_a$, i. e., the mechanical (viscous) friction coefficient has been neglected with respect to the electrical coefficient. Now the input–output transfer function of the motor can be written as

$$M(s) = \frac{k_m}{s(1 + sT_m)}, \quad (8.11)$$

where $k_m = G_v/k_v$ and $T_m = R_a J / k_v k_t$ are, respectively, the voltage-to-velocity gain and the time constant of the motor.

To guide selection of the control structure, start by noticing that an effective rejection of the disturbance d on the output θ is ensured by

1. A large value of the amplifier before the point of intervention of the disturbance
2. The presence of an integral action in the controller so as to cancel the effect of the gravitational component on the output at the steady state (i. e., constant θ).

In this case, as shown in Fig. 8.4, the types of control action with position and velocity feedback are

Fig. 8.3 Block scheme of a joint-driven system (after [8.4])

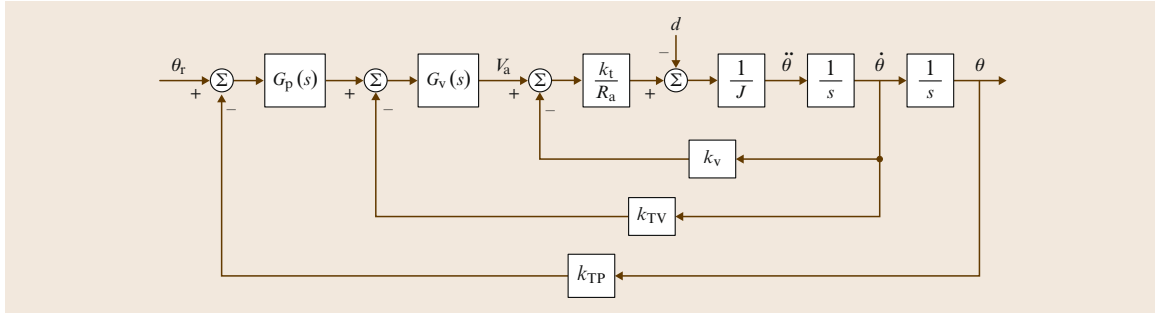

Fig. 8.4 Block scheme of position and velocity feedback (after [8.4])

characterized by [8.4]

$$G_p(s) = K_P, \quad G_v(s) = K_V \frac{1 + sT_V}{s}, \quad (8.12)$$

where $G_p(s)$ and $G_v(s)$ correspond to the position and velocity control actions, respectively. It is worth noting that the inner control action $G_v(s)$ is in a form of propositional–integral (PI) control to yield zero error in the steady state under a constant disturbance d . Furthermore, k_{TP} and k_{TV} are both transducer constants, and the amplifier gain K_V has been embedded in the gain of the inner controller. From the scheme of Fig. 8.4, the transfer function of the forward path is

$$P(s) = \frac{k_m K_P K_V (1 + sT_V)}{s(1 + sT_m)}, \quad (8.13)$$

while that of the return path is

$$H(s) = k_{TP} \left(1 + s \frac{k_{TV}}{K_P k_{TP}} \right). \quad (8.14)$$

The zero of the controller at $s = -1/T_V$ can be chosen so as to cancel the effects of the real pole of the motor at $s = -1/T_m$. Then, by setting $T_V = T_m$, the poles of the closed-loop system move on the root locus as a function of the loop gain, $k_m K_P K_V k_{TV}$. By increasing the position feedback gain K_P , it is possible to confine the closed-loop poles to a region of the complex plane with large absolute real part. Then, the actual location can be established by a suitable choice of K_V .

The closed-loop input–output transfer function is

$$\frac{\Theta(s)}{\Theta_r(s)} = \frac{\frac{1}{k_{TP}}}{1 + \frac{s k_{TP}}{K_P k_{TP}} + \frac{s^2}{k_m K_P k_{TP} K_V}}, \quad (8.15)$$

which can be compared with the typical transfer function of a second-order system

$$W(s) = \frac{\frac{1}{k_{TP}}}{1 + \frac{2\zeta s}{\omega_n} + \frac{s^2}{\omega_n^2}}. \quad (8.16)$$

It can be recognized that, with a suitable choice of the gains, it is possible to obtain any value of natural frequency ω_n and damping ratio ζ . Hence, if ω_n and ζ are given as design specifications, the following relations can be found

$$K_V k_{TV} = \frac{2\zeta \omega_n}{k_m} \quad \text{and} \quad K_P k_{TP} K_V = \frac{\omega_n^2}{k_m}. \quad (8.17)$$

For given transducer constants k_{TP} and k_{TV} , K_V and K_P will be chosen to satisfy the two equations above, respectively. On the other hand, the closed-loop disturbance/output function is

$$\frac{\Theta(s)}{D(s)} = \frac{\frac{s R_a}{k_t K_P K_{TP} K_V (1 + sT_m)}}{1 + \frac{s k_{TV}}{K_P k_{TP}} + \frac{s^2}{k_m K_P k_{TP} K_V}}, \quad (8.18)$$

which shows that the disturbance rejection factor is $X_R(s) = K_P k_{TP} K_V$ and is fixed, provided that K_V and K_P have been chosen via the approach above. Concerning the disturbance dynamics, the zero at the origin introduced by the PI, a real pole at $s = -1/T_m$, and the pair of complex poles with real part $-\zeta \omega_n$ should be kept in mind. In this case, an estimate T_R of the output recovery time needed by the control system to recover from the effect of a disturbance on the joint position can be evaluated by analyzing models of the transfer function above. Such an estimate can reasonably be expressed as $T_R = \max\{T_m, 1/\zeta \omega\}$.

8.3.2 Controller Design Based on the Multijoint Model

In recent years, independent-joint control schemes based on the complete dynamic model of the robot manipulators (i. e., a multijoint model) have been proposed. For example, following the approach of computed-torque-like control, [8.12] dealt with the regulation task for horizontal motions, and [8.13] and [8.14] handled the tracking task for arbitrary smooth trajectories. Since the overall dynamic model is considered, the effects of coupling among joints are handled. These schemes will be introduced in detail in Sect. 8.6.

8.3.3 Summary

In this section, we have presented two independent-joint control schemes: one is based on the single-joint model and the other is based on the multijoint model.

8.4 PID Control

Traditionally, control design in robot manipulators can be understood as the simple fact of tuning of a **PD** or **PID** compensator at the level of each motor driving the manipulator joints [8.1]. Fundamentally, a **PD** controller is a position and velocity feedback that has good closed-loop properties when applied to a double integrator system.

The **PID** control has a long history since *Ziegler* and *Nichols*' **PID** tuning rules were published in 1942 [8.15]. Actually, the strong point of **PID** control lies in its *simplicity* and clear physical meaning. Simple control is preferable to complex control, at least in industry, if the performance enhancement obtained by using complex control is not significant enough. The physical meanings of **PID** control [8.16] are as follows:

- *P-control* means the present effort making a present state into desired state
- *I-control* means the accumulated effort using the experience information of previous states
- *D-control* means the predictive effort reflecting the information about trends in future states.

8.4.1 PD Control for Regulation

A simple design method for manipulator control is to utilize a linear control scheme based on the linearization of the system about an operating point. An example of this method is a **PD** control with a gravity compensation scheme [8.17, 18]. Gravity compensation acts as

The former focuses on the dynamics of a single joint and regards the interaction among joints as a disturbance. This control scheme is simple but may not be suitable for high-speed tracking. Hence, we introduce the latter, which considers the overall dynamical model of robot manipulators such that the interaction among joints can be handled.

Further Reading

There are different types of feedback applied in the independent-joint control based on the single-joint model (such as pure position feedback or position, velocity, and acceleration feedback). A complete discussion is given in [8.4]. When the joint control servos are required to track reference trajectories with high speeds and accelerations, the tracking capabilities of the above schemes are inevitably degraded. A possible remedy is to adopt decentralized feedforward compensation to reduce tracking errors [8.4, 5].

a bias correction, compensating only for the amount of forces that create overshooting and an asymmetric transient behavior. Formally, it has the following form

$$\tau = \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}) - \mathbf{K}_V\dot{\mathbf{q}} + \tau_g(\mathbf{q}), \quad (8.19)$$

where \mathbf{K}_P and $\mathbf{K}_V \in R^{n \times n}$ are positive-definite gain matrices. This controller is very useful for set-point regulation, i. e., $\mathbf{q}_d = \text{constant}$ [8.7, 18]. When this controller is applied to (8.1), the closed-loop equation becomes

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{K}_V\dot{\mathbf{q}} - \mathbf{K}_P\mathbf{e}_q = \mathbf{0}, \quad (8.20)$$

where $\mathbf{e}_q = \mathbf{q}_d - \mathbf{q}$, and the equilibrium point is $\mathbf{y} = [\mathbf{e}_q^T, \dot{\mathbf{q}}^T]^T = \mathbf{0}$. Now, the stability achieved by **PD** control with gravity compensation can be analyzed according to the closed-loop dynamic (8.20). Consider the positive-definite function

$$V = \frac{1}{2}\dot{\mathbf{q}}^T \mathbf{H}(\mathbf{q})\dot{\mathbf{q}} + \frac{1}{2}\mathbf{e}_q^T \mathbf{K}_V \mathbf{e}_q.$$

Then, the derivative of function becomes negative semidefinite for any value of $\dot{\mathbf{q}}$ by using Property 8.2 in Sect. 8.1, i. e.,

$$\dot{V} = -\dot{\mathbf{q}}^T \mathbf{K}_V \dot{\mathbf{q}} \leq -\lambda_{\min}(\mathbf{K}_V) \|\dot{\mathbf{q}}\|^2, \quad (8.21)$$

where $\lambda_{\min}(\mathbf{K}_V)$ means the smallest eigenvalue of \mathbf{K}_V . By invoking the Lyapunov stability theory and LaSalle's theorem [8.1], it can be shown that the regulation error will converge asymptotically to zero, while

their high-order derivatives remain bounded. This controller requires knowledge of the gravity components (structure and parameters), though it is simple.

Now, consider simple PD control without gravity compensation

$$\tau = \mathbf{K}_P(q_d - q) - \mathbf{K}_V\dot{q}, \quad (8.22)$$

then the closed-loop dynamic equation becomes

$$\mathbf{H}(q)\ddot{q} + \mathbf{C}(q, \dot{q})\dot{q} + \tau_g(q) + \mathbf{K}_V\dot{q} - \mathbf{K}_P e_q = \mathbf{0}. \quad (8.23)$$

Consider the positive definite function

$$V = \frac{1}{2}\dot{q}^T \mathbf{H}(q)\dot{q} + \frac{1}{2}e_q^T \mathbf{K}_V e_q + U(q) + U_0,$$

where $U(q)$ denotes the potential energy with the relation of $\partial U(q)/\partial q = \tau_g(q)$ and U_0 is a suitable constant. Taking time derivative of V along the closed-loop dynamics (8.23) gives the same result (8.21) with previous one using gravity compensation. In this case, the control system must be stable in the sense of Lyapunov, but it can not conclude that the regulation error will converge to zero by LaSalle's theorem [8.1]. Actually, the system precision (the size of the regulation error vector) will depend on the size of the gain matrix \mathbf{K}_P in the following form

$$\|e_q\| \leq \|\mathbf{K}_P^{-1}\|g_0, \quad (8.24)$$

where g_0 is that in Property 8.4 in Sect. 8.1. Hence, the regulation error can be arbitrarily reduced by increasing \mathbf{K}_P ; nevertheless, measurement noise and other unmodeled dynamics, such as actuator friction, will limit the use of high gains in practice.

8.4.2 PID Control for Regulation

An integral action may be added to the previous PD control in order to deal with gravity forces, which to some extent can be considered as a constant disturbance (from the local point of view). The PID regulation controller can be written in the following general form

$$\tau = \mathbf{K}_P(q_d - q) + \mathbf{K}_I \int f(q_d - q)dt - \mathbf{K}_V\dot{q},$$

where $\mathbf{K}_I \in R^{n \times n}$ is a positive-definite gain matrix, and:

- If $f(q_d - q) = q_d - q$, we have PID control.
- If $\mathbf{K}_I \int (-\dot{q})dt$ is added, we have PI²D control.
- If $f(\cdot) = \tanh(\cdot)$, we have PD + nonlinear integral control.

Global asymptotic stability (GAS) by PID control was proved in [8.12] for robotic motion control system including external disturbances, such as Coulomb

friction. Also, Tomei proved the GAS of PD control in [8.19] by using an adaptation for gravity term. On the other hand, Ortega et al. showed in [8.20] that PI²D control could yield semiglobal asymptotic stability (SGAS) in the presence of gravity and bounded external disturbances. Also, Angeli proved in [8.21] that PD control could achieve the input-output-to-state stability (IOSS) for robotic systems. Also, Ramirez et al. proved the SGAS (with some conditions) for PID gains in [8.22]. Also, Kelly proved in [8.23] that PD plus nonlinear integral control could achieve GAS under gravity.

Actually, a large integral action in PID control can cause instability of the motion control system. In order to avoid this, the integral gain should be bounded by an upper limit of the following form [8.1]

$$\frac{k_P k_V}{\lambda_H^2} > k_I,$$

where λ_H is that in Property 8.1 in Sect. 8.1, $\mathbf{K}_P = k_P \mathbf{I}$, $\mathbf{K}_I = k_I \mathbf{I}$, and $\mathbf{K}_V = k_V \mathbf{I}$. This relation gives the guidelines for gain selection implicitly. Also, PID control has generated a great variety of PID control plus something, e.g., PID plus friction compensator, PID plus gravity compensator, PID plus disturbance observer.

8.4.3 PID Gain Tuning

The PID control can be utilized for trajectory tracking as well as set-point regulation. True tracking control will be treated after Sect. 8.5. In this section, the simple but useful PID gain tuning method will be introduced for practical use. The general PID controller can be written in the following general form

$$\tau = \mathbf{K}_V \dot{e}_q + \mathbf{K}_P e_q + \mathbf{K}_I \int e_q dt,$$

or, in another form,

$$\tau = \left(\mathbf{K} + \frac{1}{\gamma^2} \mathbf{I} \right) \left(\dot{e}_q + \mathbf{K}_P e_q + \mathbf{K}_I \int e_q dt \right). \quad (8.25)$$

In a fundamental stability analysis of tracking control systems, Qu and Dorsey proved in [8.24] that PD control could satisfy uniform ultimate boundedness (UUB). Also, Berghuis and Nijmeijer proposed output feedback PD control, which satisfies semiglobal uniform ultimate boundedness (SGUUB) in [8.25] under gravity and a bounded disturbance. Recently, Choi et al. suggested inverse optimal PID control [8.26], assuring extended disturbance input-to-state stability (ISS).

Actually, if a **PID** controller (8.25) is repeatedly applied to the same set point or desired trajectory, then the maximum error will be proportional to the gains in the following form

$$\max_{0 \leq t \leq t_f} \|e_q(t)\| \propto \frac{\gamma^2}{\sqrt{2k\gamma^2 + 1}}, \quad (8.26)$$

where t_f denotes the final execution time of a given task and $\mathbf{K} = k\mathbf{I}$. This relation can be utilized to tune the gain of a **PID** controller and is referred to as the compound tuning rule [8.16]. The compound tuning rule implicitly includes simple tuning rules as follows (γ tuning method):

- Square tuning: $\max \|e_q\| \propto \gamma^2$, for a small k
- Linear tuning: $\max \|e_q\| \propto \gamma$, for a large k .

For example, suppose we select positive constant diagonal matrices $\mathbf{K}_p = k_p\mathbf{I}$, $\mathbf{K}_I = k_I\mathbf{I}$, while satisfying $k_p^2 > 2k_I$. For small k , the maximum error will be reduced by $\frac{1}{4}$ according to the square tuning rule, if we reduce the value γ by $\frac{1}{2}$. For large k , the maximum error will be proportionally reduced as γ according to the linear tuning rule. This means that we can tune the **PID** controller using only one parameter γ when the other gain parameters are fixed [8.16] (🔗 VIDEO 25). Although these rules are very useful in tuning the control performance, they can be utilized only for repetitive experiments for the same set point or desired trajectory because the tuning rules consist of proportional relations.

8.4.4 Automatic Tuning

For simplicity, define the composite error to be

$$s(t) = \dot{e}_q + \mathbf{K}_p e_q + \mathbf{K}_I \int e_q dt.$$

Now simple auto-tuning **PID** control is suggested by choosing one tuning parameter \mathbf{K} as shown in the following control form

$$\tau = \left(\hat{K}(t) + \frac{1}{\gamma^2} \mathbf{I} \right) s(t),$$

and its automatic tuning rule as follow

$$\frac{d\hat{K}_i}{dt} = \Gamma_i s_i^2(t), \quad \text{for } i = 1, \dots, n, \quad (8.27)$$

where Γ_i implies an update gain parameter for i -th control joint.

For practical use of the **PID** control, a target performance denoted by Ω is specified in advance

$$\sup_{0 \leq t \leq t_f} |s(t)| = \Omega,$$

in order to maintain the composite error within the region Ω . Moreover, since the auto-tuning rule has the decentralized type (8.27), we suggest the decentralized criterion for auto-tuning as follows

$$|s_i| > \frac{\Omega}{\sqrt{2n}}, \quad (8.28)$$

where n is the number of the joint coordinates. As soon as the composite error arrives at the tuning region (8.28), the auto-tuning rule is implemented to assist the achievement of target performance. On the contrary, if the composite error stays in non-tuning region, namely, $|s_i| \leq \Omega/\sqrt{2n}$, then the auto-tuning process stops. For this case, we expect that the gain \hat{K} updated by an auto-tuning rule (8.27) would be larger than the matrix \mathbf{K}_Ω able to achieve the target performance Ω . As a matter of fact, the auto-tuning rule plays a nonlinear damping role in the auto-tuning region.

Matlab Example (Multimedia)

Simple automatic tuning example for one-link manipulator control system is shown in the multimedia source to help readers' understanding.

Further Reading

The **PID**-type controllers were designed to solve the regulation control problem. They have the advantage of requiring knowledge of neither the model structure nor the model parameters. Also, the stability achieved by **PID**-type controllers was presented in this section. A range of books and papers [8.1, 15, 16, 22, 27, 28] are available to the robotics audience, detailing the individual tuning methods used in **PID** control and their concrete proofs.

8.5 Tracking Control

While independent PID controls are adequate in most set-point regulation problems, there are many tasks that require effective trajectory tracking capabilities such as plasma-welding, laser-cutting or high-speed operations in the presence of obstacles. In this case, employing local schemes requires moving slowly through a number of intermediate set points, thus considerably delaying the completion of the task. Therefore, to improve the trajectory tracking performance, controllers should take account of the manipulator dynamic model via a computed-torque-like technique.

The tracking control problem in the joint or task space consists of following a given time-varying trajectory $\mathbf{q}_d(t)$ or $\mathbf{x}_d(t)$ and its successive derivatives $\dot{\mathbf{q}}_d(t)$ or $\dot{\mathbf{x}}_d(t)$ and $\ddot{\mathbf{q}}_d(t)$ or $\ddot{\mathbf{x}}_d(t)$, which describe the desired velocity and acceleration, respectively. To obtain successful performance, significant effort has been devoted to the development of model-based control strategies [8.1, 2, 7]. Among the control approaches reported in the literature, typical methods include the inverse dynamics control, the feedback linearization technique, and the passivity-based control method.

8.5.1 Inverse Dynamics Control

Though the inverse dynamics control has a theoretical background, such as the theory of feedback linearization discussed later, its starting point is mechanical engineering intuition based on cancelling nonlinear terms and decoupling the dynamics of each link. Inverse dynamics control in joint space has the form

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})\mathbf{v} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}), \quad (8.29)$$

which, applied to (8.1), yields a set of n decoupled linear systems, e.g., $\ddot{\mathbf{q}} = \mathbf{v}$, where \mathbf{v} is an auxiliary control input to be designed. Typical choices for \mathbf{v} are

$$\mathbf{v} = \ddot{\mathbf{q}}_d + \mathbf{K}_V(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}), \quad (8.30)$$

or with an integral component

$$\begin{aligned} \mathbf{v} = & \ddot{\mathbf{q}}_d + \mathbf{K}_V(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}) \\ & + \mathbf{K}_I \int (\mathbf{q}_d - \mathbf{q}) dt, \end{aligned} \quad (8.31)$$

leading to the error dynamics equation

$$\ddot{\mathbf{e}}_q + \mathbf{K}_V\dot{\mathbf{e}}_q + \mathbf{K}_P\mathbf{e}_q = \mathbf{0}$$

for an auxiliary control input (8.30), and

$$\mathbf{e}_q^{(3)} + \mathbf{K}_V\ddot{\mathbf{e}}_q + \mathbf{K}_P\dot{\mathbf{e}}_q + \mathbf{K}_I\mathbf{e}_q = \mathbf{0},$$

if an auxiliary control input (8.31) is used. Both error dynamics are exponentially stable by a suitable choice of the gain matrices \mathbf{K}_V and \mathbf{K}_P (and \mathbf{K}_I).

Alternatively, inverse dynamics control can be described in the operational space. Consider the operational space dynamics (8.9). If the following inverse dynamics control is used in the operational space,

$$\mathbf{f}_c = \boldsymbol{\Lambda}(\mathbf{q})(\ddot{\mathbf{x}}_d + \mathbf{K}_V\dot{\mathbf{e}}_x + \mathbf{K}_P\mathbf{e}_x) + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \boldsymbol{\eta}(\mathbf{q}),$$

where $\mathbf{e}_x = \mathbf{x}_d - \mathbf{x}$, the resulting error dynamics is

$$\ddot{\mathbf{e}}_x + \mathbf{K}_V\dot{\mathbf{e}}_x + \mathbf{K}_P\mathbf{e}_x = \mathbf{0}, \quad (8.32)$$

and it is also exponentially stable. One apparent advantage of using this controller is that \mathbf{K}_P and \mathbf{K}_V can be selected with a clear physical meaning in operational space. However, as can be seen in (8.10), $\boldsymbol{\Lambda}(\mathbf{q})$ becomes very large when the robot approaches singular configurations [8.8]. This means that large forces in some direction are needed to move the arm.

8.5.2 Feedback Linearization

This approach generalizes the concept of inverse dynamics of rigid manipulators. The basic idea of feedback linearization is to construct a transformation as a so-called *inner-loop control*, which exactly linearizes the nonlinear system after a suitable state space change of coordinates. One can then design a second stage or *outer-loop control* in the new coordinates to satisfy the traditional control design specifications such as tracking, disturbance rejection, etc. [8.5, 29]. The full power of the feedback linearization scheme for manipulator control becomes apparent if one includes in the dynamic description of the manipulator the transmission dynamics, such as the elasticity resulting from shaft windup, gear elasticity, etc. [8.5].

In recent years, an impressive volume of literature has emerged in the area of differential-geometric methods for nonlinear systems. Most of the results in this area are intended to give abstract coordinate-free descriptions of various geometric properties of nonlinear systems and as such are difficult for the non-mathematician to follow. It is our intention here to give only the basic idea of the feedback linearization scheme and to introduce a simple version of this technique that finds an immediate application to the manipulator control problem. The reader is referred to [8.30] for a comprehensive treatment of the feedback linearization technique using differential-geometric methods.

Let us now develop a simple approach to the determination of linear state-space representations of the

manipulator dynamics (8.1) by considering a general sort of output $\xi \in R^p$

$$\xi = h(q) + r(t), \quad (8.33)$$

where $h(q)$ is a general predetermined function of the joint coordinate $q \in R^n$ and $r(t)$ is a general predetermined time function. The control objective will be to select the joint torque inputs τ in order to make the output $\xi(t)$ go to zero.

The choice of $h(q)$ and $r(t)$ is based on the control purpose. For example, if $h(q) = -q$ and $r(t) = q_d(t)$, the desired joint space trajectory we would like the manipulator to follow, then $\xi(t) = q_d(t) - q(t) \equiv e_q(t)$ is the joint space tracking error. Forcing $\xi(t)$ to zero in this case would cause the joint variables $q(t)$ to track their desired values $q_d(t)$, resulting in a manipulator trajectory-following problem. As another example, $\xi(t)$ could represent the operational space tracking error $\xi(t) = x_d(t) - x(t) \equiv e_x(t)$. Then, controlling $\xi(t)$ to zero would result in trajectory following directly in operational space where the desired motion is usually specified.

To determine a linear state-variable model for manipulator controller design, let us simply differentiate the output $\xi(t)$ twice to obtain

$$\dot{\xi} = \frac{\partial h}{\partial q} \dot{q} + \dot{r} = T\dot{q} + \dot{r}, \quad (8.34)$$

$$\ddot{\xi} = T\ddot{q} + \dot{T}\dot{q} + \ddot{r}, \quad (8.35)$$

where we defined a $(p \times n)$ transformation matrix of the form

$$T(q) = \frac{\partial h(q)}{\partial q} = \begin{pmatrix} \frac{\partial h}{\partial q_1} & \frac{\partial h}{\partial q_2} & \cdots & \frac{\partial h}{\partial q_n} \end{pmatrix}. \quad (8.36)$$

Given the output $h(q)$, it is straightforward to compute the transformation $T(q)$ associated with $h(q)$. In the special case where ξ represents the operational space velocity error, then $T(q)$ denotes the Jacobian matrix $J(q)$.

According to (8.1),

$$\ddot{q} = H^{-1}(q)[\tau - n(q, \dot{q})], \quad (8.37)$$

with the nonlinear terms represented by

$$n(q, \dot{q}) = C(q, \dot{q})\dot{q} + \tau_g(q). \quad (8.38)$$

Then (8.35) yields

$$\ddot{\xi} = \ddot{r} + \dot{T}\dot{q} + T(q)H^{-1}(q)[\tau - n(q, \dot{q})]. \quad (8.39)$$

Define the *control input function*

$$u = \ddot{r} + \dot{T}\dot{q} + T(q)H^{-1}(q)[\tau - n(q, \dot{q})]. \quad (8.40)$$

Now we may define a state $y(t) \in R^{2p}$ by $y = (\xi \dot{\xi})$ and write the manipulator dynamics as

$$\dot{y} = \begin{pmatrix} 0 & I_p \\ 0 & 0 \end{pmatrix} y + \begin{pmatrix} 0 \\ I_p \end{pmatrix} u. \quad (8.41)$$

This is a linear state-space system of the form

$$\dot{y} = Ay + Bu, \quad (8.42)$$

driven by the control input u . Due to the special form of A and B , this system is called the *Brunovsky canonical form* and it is always controllable from $u(t)$.

Since (8.40) is said to be a *linearizing transformation* for the manipulator dynamic equation, one may invert this transformation to obtain the joint torque

$$\tau = H(q)T^+(q)(u - \ddot{r} - \dot{T}\dot{q}) + n(q, \dot{q}), \quad (8.43)$$

where T^+ denotes the *Moore–Penrose inverse* of the transformation matrix $T(q)$.

In the special case $\xi = e_q(t)$, and if we select $u(t)$ so that (8.41) is stable by the PD feedback $u = -K_P \xi - K_V \dot{\xi}$, then $T = -I_n$ and the control input torque $\tau(t)$ defined by (8.43) makes the manipulator move in such a way that $y(t)$ goes to zero. In this case, the feedback linearizing control and the inverse dynamics control become the same.

8.5.3 Passivity-Based Control

This method explicitly uses the passivity properties of the Lagrangian system [8.31, 32]. In comparison with the inverse dynamics method, passivity-based controllers are expected to have better robust properties because they do not rely on the exact cancellation of the manipulator nonlinearities. The passivity-based control input is given by

$$\begin{aligned} \dot{q}_r &= \dot{q}_d + \alpha e_q, \quad \alpha > 0, \\ \tau &= H(q)\ddot{q}_r + C(q, \dot{q})\dot{q}_r + \tau_g(q) + K_V \dot{e}_q + K_P e_q. \end{aligned} \quad (8.44)$$

With (8.44), we obtain the following closed-loop system

$$H(q)\dot{s}_q + C(q, \dot{q})s_q + K_V \dot{e}_q + K_P e_q = 0, \quad (8.45)$$

where $s_q = \dot{e}_q + \alpha e_q$. Let us choose a Lyapunov function $V(y, t)$ as follows

$$V = \frac{1}{2} y^T \begin{pmatrix} \alpha K_V + K_P + \alpha^2 H & \alpha H \\ \alpha H & H \end{pmatrix} y = \frac{1}{2} y^T P y. \quad (8.46)$$

Since the above equation is positive definite, it has a unique equilibrium at the origin, i. e., $\mathbf{y} = (\mathbf{e}_q^T, \dot{\mathbf{e}}_q^T)^T = \mathbf{0}$. Moreover, V can be bounded by

$$\sigma_m \|\mathbf{y}\|^2 \leq \mathbf{y}^T \mathbf{P} \mathbf{y} \leq \sigma_M \|\mathbf{y}\|^2, \quad \sigma_M \geq \sigma_m > 0. \quad (8.47)$$

The time derivative of V gives

$$\dot{V} = -\dot{\mathbf{e}}_q^T \mathbf{K}_V \dot{\mathbf{e}}_q - \alpha \mathbf{e}_q^T \mathbf{K}_P \mathbf{e}_q = -\mathbf{y}^T \mathbf{Q} \mathbf{y} < 0, \quad (8.48)$$

where $\mathbf{Q} = \text{diag}[\alpha \mathbf{K}_P, \mathbf{K}_V]$. Since \mathbf{Q} is positive definite and quadratic in \mathbf{y} , it can be also bounded by

$$\kappa_m \|\mathbf{y}\|^2 \leq \mathbf{y}^T \mathbf{Q} \mathbf{y} \leq \kappa_M \|\mathbf{y}\|^2, \quad \kappa_M \geq \kappa_m > 0. \quad (8.49)$$

Then, from the bound of the Lyapunov function V , we get

$$\dot{V} \leq -\kappa_m \|\mathbf{y}\|^2 = -2\eta V, \quad \eta = \frac{\kappa_m}{\sigma_M}, \quad (8.50)$$

which finally yields

$$V(t) \leq V(0)e^{-2\eta t}. \quad (8.51)$$

It has been shown that the value of α affects the tracking result dramatically [8.33]. The manipulator tends to vibrate for small values of α . Larger values of α allow better tracking performance and protect \mathbf{s}_q from being spoiled by the velocity measurement noise when the position error is small. In [8.34], it was suggested that

$$\mathbf{K}_P = \alpha \mathbf{K}_V \quad (8.52)$$

be used for quadratic optimization.

8.5.4 Summary

In this section, we have reviewed some of the model-based motion control methods proposed to date. Under some control approaches, the closed-loop system has either asymptotic stability or globally exponential stability. However, such ideal performance cannot be obtained in practical implementation because factors such as sampling rate, measurement noise, disturbances, and unmodeled dynamics will limit the achievable gain and the performance of the control algorithms [8.33, 35, 36].

8.6 Computed-Torque Control

Through the years many kinds of robot control schemes have been proposed. Most of these can be considered as special cases of the class of computed-torque control (Fig. 8.5) which is the technique of applying feedback linearization to nonlinear systems in general [8.37, 38]. In the section, computed-torque control will be first introduced, and its variant, so-called computed-torque-like control, will be introduced later.

8.6.1 Computed-Torque Control

Consider the control input (8.29)

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q}) \mathbf{v} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}),$$

which is also known as computed-torque control; it consists of an inner nonlinear compensation loop and an

outer loop with an exogenous control signal \mathbf{v} . Substituting this control law into the dynamical model of the robot manipulator, it follows that

$$\ddot{\mathbf{q}} = \mathbf{v}. \quad (8.53)$$

It is important to note that this control input converts a complicated nonlinear controller design problem into a simple design problem for a linear system consisting of n decoupled subsystems. One approach to the outer-loop control \mathbf{v} is propositional-derivative (PD) feedback, as in (8.30)

$$\mathbf{v} = \ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q,$$

in which case the overall control input becomes

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})(\ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q) + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}),$$

and the resulting linear error dynamics are

$$\ddot{\mathbf{e}}_q + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q = \mathbf{0}. \quad (8.54)$$

According to linear system theory, convergence of the tracking error to zero is guaranteed [8.29, 39].

Remark 8.2

One usually lets \mathbf{K}_V and \mathbf{K}_P be $(n \times n)$ diagonal positive-definite gain matrices (i. e., $\mathbf{K}_V = \text{diag}(k_{v,1},$

Fig. 8.5 Computed-torque control

$\dots, k_{v,n}) > \mathbf{0}$, $\mathbf{K}_P = \text{diag}(k_{p,1}, \dots, k_{p,n}) > \mathbf{0}$) to guarantee the stability of the error system. However, the format of the foregoing control never leads to *independent joint control* because the outer-loop multiplier $\mathbf{H}(\mathbf{q})$ and the full nonlinear compensation term $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q})$ in the inner loop scramble all joint signals among different control channels.

8.6.2 Computed-Torque-Like Control

It is worth noting that the implementation of computed-torque control requires that parameters of the dynamical model are accurately known and the control input is computed in real time. In order to avoid those problems, several variations of this control scheme have been proposed, for example, computed-torque-like control. An entire class of computed-torque-like controllers can be obtained by modifying the computed-torque control as

$$\boldsymbol{\tau} = \hat{\mathbf{H}}(\mathbf{q})\mathbf{v} + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \hat{\boldsymbol{\tau}}_g(\mathbf{q}), \quad (8.55)$$

where $\hat{\cdot}$ represents the computed or nominal value and indicates that the theoretically exact feedback linearization cannot be achieved in practice due to the uncertainty in the systems. The overall control scheme is depicted in Fig. 8.6.

Computed-Torque-Like Control with Variable-Structure Compensation

Since there is parametric uncertainty, compensation is required in the outer-loop design to achieve trajectory tracking. The following shows a computed-torque-like control with variable-structure compensation

$$\mathbf{v} = \ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q + \Delta \mathbf{v}, \quad (8.56)$$

where the variable-structure compensation $\Delta \mathbf{v}$ is devised as

$$\Delta \mathbf{v} = \begin{cases} -\rho(\mathbf{x}, t) \frac{\mathbf{B}^T \mathbf{P} \mathbf{x}}{\|\mathbf{B}^T \mathbf{P} \mathbf{x}\|} & \text{if } \|\mathbf{B}^T \mathbf{P} \mathbf{x}\| \neq 0, \\ 0 & \text{if } \|\mathbf{B}^T \mathbf{P} \mathbf{x}\| = 0, \end{cases} \quad (8.57)$$

Fig. 8.6 Computed-torque-like control

where $\mathbf{x} = (\mathbf{e}_q^T, \dot{\mathbf{e}}_q^T)^T$, $\mathbf{B} = (\mathbf{0}, \mathbf{I}_n)^T$, \mathbf{P} is a $(2n \times 2n)$ symmetric positive-definite matrix satisfying

$$\mathbf{P}\mathbf{A} + \mathbf{A}^T\mathbf{P} = -\mathbf{Q}, \quad (8.58)$$

with \mathbf{A} being defined as

$$\mathbf{A} = \begin{pmatrix} \mathbf{0} & \mathbf{I}_n \\ -\mathbf{K}_P & -\mathbf{K}_V \end{pmatrix}, \quad (8.59)$$

\mathbf{Q} being any appropriate $(2n \times 2n)$ symmetric positive-definite matrix,

$$\rho(\mathbf{x}, t) = \frac{1}{1 - \alpha} [\alpha\beta + \|\mathbf{K}\| \|\mathbf{x}\| + \bar{\mathbf{H}}\phi(\mathbf{x}, t)], \quad (8.60)$$

where α and β are positive constants such that $\|\mathbf{H}^{-1}(\mathbf{q})\hat{\mathbf{H}}(\mathbf{q}) - \mathbf{I}_n\| \leq \alpha < 1$ for all $\mathbf{q} \in R^n$ and $\sup_{t \in [0, \infty)} \|\ddot{\mathbf{q}}_d(t)\| < \beta$, respectively, \mathbf{K} is the $(n \times 2n)$ matrix defined as $\mathbf{K} = [\mathbf{K}_P, \mathbf{K}_V]$, $\bar{\lambda}_H$ being a positive constant such that $\|\mathbf{H}^{-1}(\mathbf{q})\| \leq \bar{\lambda}_H$ for all $\mathbf{q} \in R^n$, and the function ϕ being defined as

$$\begin{aligned} & \|[\hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) - \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})]\dot{\mathbf{q}} + [\hat{\boldsymbol{\tau}}_g(\mathbf{q}) - \boldsymbol{\tau}_g(\mathbf{q})]\| \\ & \leq \phi(\mathbf{x}, t). \end{aligned} \quad (8.61)$$

Convergence of the tracking error to zero can be shown using the Lyapunov function

$$V = \mathbf{x}^T \mathbf{P} \mathbf{x}, \quad (8.62)$$

following the stability analysis in [8.5, 40].

Remarks 8.3

- By Property 8.1 in Sect. 8.1, there exist positive constants $\bar{\lambda}_H$ and $\bar{\lambda}_h$ such that $\bar{\lambda}_h \leq \|\mathbf{H}^{-1}(\mathbf{q})\| \leq \bar{\lambda}_H$ for all $\mathbf{q} \in R^n$. If we choose

$$\hat{\mathbf{H}} = \frac{1}{c} \mathbf{I}_n, \quad \text{where } c = \frac{\bar{\lambda}_H + \bar{\lambda}_h}{2}, \quad (8.63)$$

it can be shown that

$$\|\mathbf{H}^{-1}(\mathbf{q})\hat{\mathbf{H}}(\mathbf{q}) - \mathbf{I}_n\| \leq \frac{\bar{\lambda}_H - \bar{\lambda}_h}{\bar{\lambda}_H + \bar{\lambda}_h} \equiv \alpha < 1, \quad (8.64)$$

which indicates that there is always at least one choice of $\hat{\mathbf{H}}$ for some $\alpha < 1$.

- Due to the discontinuity in $\Delta \mathbf{v}$, chattering phenomenon may occur when the control scheme is applied. It is worth noting that chattering is often undesirable since the high-frequency component in

the control can excite unmodeled dynamic effect (such as joint flexibility) [8.6, 29, 38]. In order to avoid chattering, the variable-structure compensation can be modified to become smooth, i. e.,

$$\Delta \mathbf{v} = \begin{cases} -\rho(\mathbf{x}, t) \frac{\mathbf{B}^T \mathbf{P} \mathbf{x}}{\|\mathbf{B}^T \mathbf{P} \mathbf{x}\|} & \text{if } \|\mathbf{B}^T \mathbf{P} \mathbf{x}\| > \varepsilon, \\ -\frac{\rho(\mathbf{x}, t)}{\varepsilon} \mathbf{B}^T \mathbf{P} \mathbf{x} & \text{if } \|\mathbf{B}^T \mathbf{P} \mathbf{x}\| \leq \varepsilon, \end{cases} \quad (8.65)$$

where ε is a positive constant and is used as the boundary layer. Following this modification, convergence of tracking errors to a residual set can be ensured, and the size of this residual set can be made smaller by use of a smaller value of ε .

Computed-Torque-Like Control with Independent-Joint Compensation

Obviously, the previous compensation scheme is centralized, which implies that the online computation load is heavy and high-cost hardware is required for practical implementation. In order to solve this problem, a scheme with independent-joint compensation is introduced below. In this scheme, a computed-torque-like control is designed with estimates as

$$\hat{\mathbf{H}}(\mathbf{q}) = \mathbf{I}, \quad \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{0}, \quad \hat{\boldsymbol{\tau}}(\mathbf{q}) = \mathbf{0}. \quad (8.66)$$

Then, we use the outer-loop \mathbf{v} as

$$\mathbf{v} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q + \Delta \mathbf{v}, \quad (8.67)$$

where the positive constants \mathbf{K}_P and \mathbf{K}_V are selected to be sufficiently large, and the i -th component Δv_i of $\Delta \mathbf{v} = (\mathbf{v}_1, \dots, \mathbf{v}_n)^T$ is

$$\Delta v_i = \begin{cases} -[\beta^T \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d)]^2 \frac{s_i}{\varepsilon_i} & \text{if } |s_i| \leq \frac{\varepsilon_i}{\beta^T \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d)}, \\ -\beta^T \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \frac{s_i}{|s_i|} & \text{if } |s_i| > \frac{\varepsilon_i}{\beta^T \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d)}. \end{cases} \quad (8.68)$$

In this compensation, $s_i = \dot{e}_{q,i} + \lambda_i e_{q,i}$, $i \in \{1, \dots, n\}$, and $\lambda_i, i \in \{1, \dots, n\}$ are positive constants. Furthermore, following the properties of robot manipulators, we have

$$\begin{aligned} & \|\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}}_d + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}_d + \boldsymbol{\tau}_g(\mathbf{q})\| \\ & \leq \beta_1 + \beta_2 \|\mathbf{q}\| + \|\dot{\mathbf{q}}\| = \beta^T \mathbf{w}(\mathbf{q}, \dot{\mathbf{q}}) \end{aligned}$$

for some suitable positive constants β_1 , β_2 , and β_3 , where $\boldsymbol{\beta} = (\beta_1, \beta_2, \beta_3)^T$ and

$$\mathbf{w}(\mathbf{q}, \dot{\mathbf{q}}) = [1, \|\mathbf{q}\|, \|\dot{\mathbf{q}}\|]^T. \quad (8.69)$$

Finally, ε_i , $i \in \{1, \dots, n\}$, is the variable length of the boundary layer, satisfying

$$\dot{\varepsilon}_i = -g_i \varepsilon_i, \quad \varepsilon(0) > 0, \quad g_i > 0. \quad (8.70)$$

It is worth pointing out that the term \mathbf{w} in this control scheme is devised as the desired compensation rather than feedback. Furthermore, this scheme is in a form of independent-joint control and hence has the advantages introduced before. The convergence of the tracking error to zero can be shown using the Lyapunov function

$$V = \frac{1}{2} (\mathbf{e}_q^T \dot{\mathbf{e}}_q^T) \begin{pmatrix} \lambda \mathbf{K}_P & \mathbf{H} \\ \mathbf{H} & \lambda \mathbf{H} \end{pmatrix} \begin{pmatrix} \mathbf{e}_q \\ \dot{\mathbf{e}}_q \end{pmatrix} + \sum_{i=1}^n g_i^{-1} \varepsilon_i, \quad (8.71)$$

whose time derivative along the trajectory of the closed-loop systems follows

$$\dot{V} = -\alpha \left\| \begin{pmatrix} \mathbf{e}_q \\ \dot{\mathbf{e}}_q \end{pmatrix} \right\|^2, \quad (8.72)$$

with α being some positive constant, if sufficiently large \mathbf{K}_P and γ are used. The detailed analysis of stability, which requires Properties 8.3 and 8.4, can be found in [8.13].

Remark 8.3

Similar to computed-torque-like control with variable-structure compensation, we can consider the nonzero boundary layer as

$$\dot{\varepsilon}_i = -g_i \varepsilon_i, \quad \varepsilon(0) > 0, \quad g_i, \alpha_i > 0. \quad (8.73)$$

Following this modification, tracking errors converge to a residual set. The size of this residual set can be made smaller by the use of a smaller value of ε (i. e., smaller α_i).

For the task of point-to-point control, one PD controller with gravity compensation is designed with the estimates

$$\hat{\mathbf{H}}(\mathbf{q}) = \mathbf{I}, \quad \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{0}, \quad \hat{\boldsymbol{\tau}}(\mathbf{q}) = \boldsymbol{\tau}_g(\mathbf{q}), \quad (8.74)$$

with $\boldsymbol{\tau}_g(\mathbf{q})$ being the gravity term of the dynamical model of the robot manipulators. Then, we use the outer-loop \mathbf{v} as

$$\mathbf{v} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \quad (8.75)$$

such that the control input becomes

$$\boldsymbol{\tau} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q + \boldsymbol{\tau}_g(\mathbf{q}). \quad (8.76)$$

This scheme is much simpler to implement than the exact computed-torque controller. The convergence of the tracking error to zero can be shown using the Lyapunov function

$$V = \frac{1}{2} \dot{e}_q^T \mathbf{H}(q) \dot{e}_q + \frac{1}{2} e_q^T \mathbf{K}_p e_q, \quad (8.77)$$

whose time derivative along the solution trajectories of the closed-loop system is

$$\dot{V} = -\dot{e}_q^T \mathbf{K}_v \dot{e}_q. \quad (8.78)$$

The detailed analysis of stability is given in [8.12]. It is necessary to note that this result is for the case of regulation, rather than for the case of tracking, since the former theoretical base, which relies on LaSalle's lemma, requires the system be autonomous (time invariant) [8.38, 41, 42].

Remark 8.4

If we neglect gravity in the dynamical model of the robot manipulators, then the gravity estimation can be omitted here, i. e., $\hat{\tau}_g(q) = \mathbf{0}$, so that the control law becomes

$$\tau = v = \mathbf{K}_v \dot{e}_q + \mathbf{K}_p e_q, \quad (8.79)$$

8.7 Adaptive Control

An adaptive controller differs from an ordinary controller in that the controller parameters are time varying, and there is a mechanism for adjusting these parameters online based on some signals in the closed-loop systems. By the use of such control scheme, the control goal can be achieved even if there is parametric uncertainty in the plant. In this section, we will introduce several adaptive control schemes to deal with the case of imperfect knowledge of dynamical parameters of the robot manipulators. The control performance of those adaptive control schemes, including adaptive computed-torque control, adaptive inertia-related control, adaptive control based on passivity, and adaptive control with desired compensation, are basically derived from Property 8.5. Finally, the condition of persistent excitation, which is important in parameter convergence, will be addressed.

8.7.1 Adaptive Computed-Torque Control

The computed-torque control scheme is appealing, since it allows the designer to transform a MIMO highly coupled nonlinear system into a very simple decoupled

linear system, whose control design is a well-established problem. However, this method of feedback linearization relies on perfect knowledge of the system parameters, and failure to have this will cause erroneous parametric estimates, resulting in a mismatch term in the closed-loop model of the error system. That term can be interpreted as a nonlinear perturbation acting at the input of the closed-loop system. In order to solve the problem due to parametric uncertainty, we instead consider the inverse dynamics method with parameter estimates of

$$\tau = \hat{\mathbf{H}}(q)(\ddot{q}_d + \mathbf{K}_v \dot{e}_q + \mathbf{K}_p e_q) + \hat{\mathbf{C}}(q, \dot{q})\dot{q} + \hat{\tau}_g(q), \quad (8.80)$$

where $\hat{\mathbf{H}}$, $\hat{\mathbf{C}}$, $\hat{\tau}_g$ have the same functional form as \mathbf{H} , \mathbf{C} , τ_g . From Property 8.5 of the dynamics model, we have

$$\hat{\mathbf{H}}(q)\ddot{q} + \hat{\mathbf{C}}(q, \dot{q})\dot{q} + \hat{\tau}_g(q) = \mathbf{Y}(q, \dot{q}, \ddot{q})\hat{a}, \quad (8.81)$$

where $\mathbf{Y}(q, \dot{q}, \ddot{q})$, called the regressor, is a known $(n \times r)$ function matrix and \hat{a} is the $(r \times 1)$ vector that summarizes all the estimated parameters. Substituting this

8.6.3 Summary

In this section, we have presented two control schemes: the computed-torque and computed-torque-like control. The former transforms a multi-input multi-output (MIMO) nonlinear robotic system into a very simple decoupled linear closed-loop system whose control design is a well-established problem. Since the practical implementation of the former control requires pre-knowledge of all the manipulator parameters and its payload, which may not be realistic, the latter was introduced to relax the foregoing requirement and still to achieve the objective of tracking subject to system's uncertainty.

Further Reading

The PD control with different feedforward compensation for tracking control is investigated in [8.43]. An adaptive control scheme based on PD control is presented in [8.19].

control input τ into the manipulator dynamics gives the following closed-loop error model

$$\hat{\mathbf{H}}(q)(\ddot{e}_q + \mathbf{K}_v \dot{e}_q + \mathbf{K}_p e_q) = \mathbf{Y}(q, \dot{q}, \ddot{q})\tilde{a}, \quad (8.82)$$

where $\tilde{a} = \hat{a} - a$. In order to acquire an appropriate adaptive law, we first assume that the acceleration term \ddot{q} is measurable, and that the estimated inertia matrix $\hat{\mathbf{H}}(q)$ is never singular. Now, for convenience, the error equation is rewritten as

$$\dot{x} = \mathbf{A}x + \mathbf{B}\hat{\mathbf{H}}^{-1}(q)\mathbf{Y}(q, \dot{q}, \ddot{q})\tilde{a}, \quad (8.83)$$

with $x = (e_q^T, \dot{e}_q^T)^T$,

$$\mathbf{A} = \begin{pmatrix} \mathbf{0}_n & \mathbf{I}_n \\ -\mathbf{K}_p & -\mathbf{K}_v \end{pmatrix}, \quad \mathbf{B} = \begin{pmatrix} \mathbf{0}_n \\ \mathbf{I}_n \end{pmatrix}. \quad (8.84)$$

The adaptive law is considered as

$$\dot{\hat{a}} = -\mathbf{\Gamma}^{-1}\mathbf{Y}^T(q, \dot{q}, \ddot{q})\hat{\mathbf{H}}^{-1}(q)\mathbf{B}^T\mathbf{P}x, \quad (8.85)$$

where $\mathbf{\Gamma}$ is an $(r \times r)$ positive-definite constant matrix, and \mathbf{P} is a $(2n \times 2n)$ symmetric positive-definite constant matrix satisfying

$$\mathbf{P}\mathbf{A} + \mathbf{A}^T\mathbf{P} = -\mathbf{Q}, \quad (8.86)$$

with \mathbf{Q} being a symmetric positive-definite constant matrix with coherent dimension. In this adaptive law, we made two assumptions:

- The joint acceleration \ddot{q} is measurable, and
- The bounded range of the unknown parameter is available.

The first assumption is to ensure that the regressor $\mathbf{Y}(q, \dot{q}, \ddot{q})$ is known a priori, whereas the second assumption is to allow one to keep the estimate $\hat{\mathbf{H}}(q)$ nonsingular by restricting the estimated parameter \hat{a} to lie within a range about the true parameter value.

Convergence of the tracking error and maintaining boundedness of all internal signals can actually be guaranteed by Lyapunov stability theory with the Lyapunov function

$$\dot{V} = -x^T\mathbf{Q}x. \quad (8.87)$$

Detailed stability analysis is given in [8.2].

Remark 8.5

For practical and theoretical reasons, the first assumption above is hardly acceptable. In most cases, it is not easy to obtain an accurate measure of acceleration; the robustness of the above adaptive control scheme with

respect to such a disturbance has to be established. Moreover, from a pure theoretical viewpoint, measuring q, \dot{q}, \ddot{q} means that not only do we need the whole system state vector, but we also need its derivative.

8.7.2 Adaptive Inertia-Related Control

Another adaptive control scheme is now introduced. This proposed scheme does not require the measurement of the manipulator's acceleration nor does it require inversion of the estimated inertia matrix. Hence, the drawbacks of the adaptive computed-torque control scheme are avoided. Let us consider the control input

$$\tau = \hat{\mathbf{H}}(q)\dot{v} + \hat{\mathbf{C}}(q, \dot{q})v + \hat{\tau}_g(q) + \mathbf{K}_D s, \quad (8.88)$$

where the auxiliary signals v and s are defined as $v = \dot{q}_d + \mathbf{\Lambda}e_q$ and $s = v - \dot{q} = \dot{e}_q + \mathbf{\Lambda}e_q$, with $\mathbf{\Lambda}$ being an $(n \times n)$ positive-definite matrix. Following Property 8.5 of the dynamic model, we have

$$\mathbf{H}(q)\dot{v} + \mathbf{C}(q, \dot{q})v + \tau_g(q) = \bar{\mathbf{Y}}(q, \dot{q}, v, \dot{v})a, \quad (8.89)$$

where $\bar{\mathbf{Y}}(\cdot, \cdot, \cdot, \cdot)$ is an $(n \times r)$ matrix of known time functions. The formulation above is the same type of the parameter separation that was used in the formulation of the adaptive computed-torque control. Note that $\bar{\mathbf{Y}}(q, \dot{q}, v, \dot{v})$ is independent of the joint acceleration. Similar to the formulation above, we also have

$$\hat{\mathbf{H}}(q)\dot{v} + \hat{\mathbf{C}}(q, \dot{q})v + \hat{\tau}_g(q) = \bar{\mathbf{Y}}(q, \dot{q}, v, \dot{v})\hat{a}. \quad (8.90)$$

Substituting the control input into the equation of motion, it follows that

$$\begin{aligned} & \mathbf{H}(q)\ddot{q} + \mathbf{C}(q, \dot{q})\dot{q} + \tau_g(q) \\ &= \hat{\mathbf{H}}(q)\dot{v} + \hat{\mathbf{C}}(q, \dot{q})v + \hat{\tau}_g(q) + \mathbf{K}_D s. \end{aligned}$$

Since $\ddot{q} = \dot{v} - \dot{s}$, $\dot{q} = v - s$, the previous result can be rewritten as

$$\mathbf{H}(q)\dot{s} + \mathbf{C}(q, \dot{q})s + \mathbf{K}_D s = \bar{\mathbf{Y}}(q, \dot{q}, v, \dot{v})\tilde{a}, \quad (8.91)$$

where $\tilde{a} = a - \hat{a}$. The adaptive law is considered as

$$\dot{\hat{a}} = \mathbf{\Gamma}\bar{\mathbf{Y}}^T(q, \dot{q}, v, \dot{v})s. \quad (8.92)$$

The convergence of the tracking error to zero with boundedness on all internal signals can be shown

through Lyapunov stability theory using the following Lyapunov-like function

$$V = \frac{1}{2} \mathbf{s}^T \mathbf{H}(\mathbf{q}) \mathbf{s} + \frac{1}{2} \tilde{\mathbf{a}}^T \mathbf{\Gamma}^{-1} \tilde{\mathbf{a}}, \quad (8.93)$$

whose time derivative along the trajectories of the closed-loop systems can be found to be

$$\dot{V} = -\mathbf{s}^T \mathbf{K}_D \mathbf{s}. \quad (8.94)$$

The detailed stability analysis is given in [8.32].

Remark 8.6

- The restrictions for adaptive computed-torque control formerly seen have been removed here.
- The term $\mathbf{K}_D \mathbf{s}$ introduces a PD-type linear stabilizing control action to the error system model.
- The estimated parameters converge to the true parameters provided the reference trajectory satisfies the condition of persistency of excitation,

$$\begin{aligned} \alpha_1 \mathbf{I}_r &\leq \int_{t_0}^{t_0+t} \mathbf{Y}^T(\mathbf{q}_d, \dot{\mathbf{q}}_d, \mathbf{v}, \dot{\mathbf{v}}) \mathbf{Y}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \mathbf{v}, \dot{\mathbf{v}}) dt \\ &\leq \alpha_2 \mathbf{I}_r, \end{aligned}$$

for all t_0 , where α_1 , α_2 , and t are all positive constants.

8.7.3 Adaptive Control Based on Passivity

Taking a physics viewpoint of control, we see that the concept of passivity has become popular for the development of adaptive control schemes. Here, we illustrate how the concept of passivity can be used to design a class of adaptive control laws for robot manipulators. First, we define an auxiliary filtered tracking error signal \mathbf{r} as

$$\mathbf{r} = \mathbf{F}^{-1}(s) \mathbf{e}_q, \quad (8.95)$$

where

$$\mathbf{F}^{-1}(s) = \left[s \mathbf{I}_n + \frac{1}{s} \mathbf{K}(s) \right], \quad (8.96)$$

and s is the Laplace transform variable. The $(n \times n)$ matrix $\mathbf{K}(s)$ is chosen such that $\mathbf{F}(s)$ is a strictly proper, stable transfer function matrix. As in the preceding schemes, the adaptive control strategies has close ties to the ability to separate the known functions from the

unknown constant parameters. We use the expression given above to define

$$\begin{aligned} \mathbf{Z}\boldsymbol{\varphi} &= \mathbf{H}(\mathbf{q})[\ddot{\mathbf{q}}_d + \mathbf{K}(s)\mathbf{e}_q] \\ &\quad + \mathbf{V}(\mathbf{q}, \dot{\mathbf{q}}) \left[\dot{\mathbf{q}}_n + \frac{1}{s} \mathbf{K}(s)\mathbf{e}_q \right] + \boldsymbol{\tau}_g(\mathbf{q}), \end{aligned}$$

where \mathbf{Z} is a known $(n \times r)$ regression matrix and $\boldsymbol{\varphi}$ is a vector of unknown system parameters in the adaptive context. It is important to note that the above can be arranged such that \mathbf{Z} and \mathbf{r} do not depend on the measurement of the joint acceleration $\ddot{\mathbf{q}}$. The adaptive control scheme given here is called the passivity approach because the mapping of $-\mathbf{r} \rightarrow \mathbf{Z}\boldsymbol{\varphi}$ is constructed to be a passive mapping. That is, we develop an adaptive law such that

$$\int_0^t -\mathbf{r}^T(\sigma) \mathbf{Z}(\sigma) \tilde{\boldsymbol{\varphi}}(\sigma) d\sigma \geq -\beta \quad (8.97)$$

is satisfied for all time and for some positive scalar constant β . For this class of adaptive controllers, the control input is given by

$$\boldsymbol{\tau} = \mathbf{Z}\hat{\boldsymbol{\varphi}} + \mathbf{K}_D \mathbf{r}, \quad (8.98)$$

Detailed analysis of stability is given in [8.44].

Remarks 8.4

- If $\mathbf{K}(s)$ is selected such that $\mathbf{H}(s)$ has a relative degree of one, \mathbf{Z} and \mathbf{r} will not depend on $\ddot{\mathbf{q}}$.
- Many types of control schemes can be generated from the adaptive passive control approach by selected different transfer function matrices $\mathbf{K}(s)$ in the definition of \mathbf{r} .
- Note that, by defining $\mathbf{K}(s) = s\boldsymbol{\Lambda}$ such that $\mathbf{F}(s) = (s\mathbf{I}_n + \boldsymbol{\Lambda})^{-1}$, we have the control input

$$\boldsymbol{\tau} = \mathbf{Z}\hat{\boldsymbol{\varphi}} - \mathbf{K}_D \mathbf{r},$$

with

$$\begin{aligned} \mathbf{Z}\hat{\boldsymbol{\varphi}} &= \hat{\mathbf{H}}(\mathbf{q})(\ddot{\mathbf{q}}_d + \boldsymbol{\Lambda}\dot{\mathbf{e}}_q) + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})(\dot{\mathbf{q}}_d + \boldsymbol{\Lambda}\mathbf{e}_q) \\ &\quad + \hat{\boldsymbol{\tau}}_g(\mathbf{q}). \end{aligned}$$

The adaptive law may be chosen as

$$\dot{\hat{\boldsymbol{\varphi}}} = \mathbf{\Gamma} \mathbf{Z}^T (\dot{\mathbf{e}}_q + \boldsymbol{\Lambda}\mathbf{e}_q)$$

to satisfy the condition of passive mapping. This indicates that adaptive inertia-related control can be viewed as a special case of adaptive passive control.

8.7.4 Adaptive Control with Desired Compensation

In order to implement the adaptive control scheme, one needs to calculate the elements of $\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ in real time. However, this procedure may be excessively time consuming since it involves computations with highly nonlinear functions of joint position and velocity. Consequently, the real-time implementation of such a scheme is rather difficult. To overcome this difficulty, the adaptive control with desired compensation was proposed and is discussed here. In other words, the variables \mathbf{q} , $\dot{\mathbf{q}}$, and $\ddot{\mathbf{q}}$ are replaced with the desired ones, namely, \mathbf{q}_d , $\dot{\mathbf{q}}_d$, and $\ddot{\mathbf{q}}_d$. Since the desired quantities are known in advance, all their corresponding calculations can be performed offline, which renders real-time implementation more plausible. Let us consider the control input

$$\boldsymbol{\tau} = \mathbf{Y}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)\hat{\mathbf{a}} + k_a \mathbf{s} + k_p \mathbf{e}_q + k_n \|\mathbf{e}_q\|^2 \mathbf{s}, \quad (8.99)$$

where the positive constants k_a , k_p , and k_n are sufficiently large, and the auxiliary signal \mathbf{s} is defined as $\mathbf{s} = \dot{\mathbf{e}}_q + \mathbf{e}_q$. The adaptive law is considered as

$$\dot{\hat{\mathbf{a}}} = -\boldsymbol{\Gamma} \mathbf{Y}^T(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d) \mathbf{s}. \quad (8.100)$$

It is worth noting that the desired compensation is adopted in both the control and adaptive laws such that the computational load can be drastically reduced. For the sake of this analysis, we note that

$$\begin{aligned} & \|\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})\mathbf{a} - \mathbf{Y}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)\hat{\mathbf{a}}\| \\ & \leq \zeta_1 \|\mathbf{e}_q\| + \zeta_2 \|\mathbf{e}_q\|^2 + \zeta_3 \|\mathbf{s}\| + \zeta_4 \|\mathbf{s}\| \|\mathbf{e}_q\|, \end{aligned}$$

where ζ_1 , ζ_2 , ζ_3 , and ζ_4 are positive constants. In order to achieve trajectory tracking, it is required that

$$\begin{aligned} k_a & > \zeta_2 + \zeta_4, \\ k_p & > \frac{\zeta_1}{2} + \frac{\zeta_2}{4}, \\ k_v & > \frac{\zeta_1}{2} + \zeta_3 + \frac{\zeta_2}{4}, \end{aligned}$$

(i.e., the gains k_a , k_p , and k_v must be sufficiently large). The convergence of the tracking error to zero with boundedness on all internal signals can be proved through application of Lyapunov stability theory with the following Lyapunov-like function

$$V = \frac{1}{2} \mathbf{s}^T \mathbf{H}(\mathbf{q}) \mathbf{s} + \frac{1}{2} k_p \mathbf{e}_q^T \mathbf{e}_q + \frac{1}{2} \tilde{\mathbf{a}}^T \boldsymbol{\Gamma}^{-1} \tilde{\mathbf{a}}, \quad (8.101)$$

whose time derivative along the trajectories of the closed-loop system can be derived as

$$\dot{V} \leq -\mathbf{x}^T \mathbf{Q} \mathbf{x}, \quad (8.102)$$

where

$$\begin{aligned} \mathbf{x} &= \begin{pmatrix} \|\mathbf{e}_q\| \\ \|\mathbf{s}\| \end{pmatrix}, \\ \mathbf{Q} &= \begin{pmatrix} \frac{k_p - \zeta_2}{4} & \frac{-\zeta_1}{2} \\ \frac{-\zeta_1}{2} & \frac{k_v - \zeta_3 - \zeta_4}{4} \end{pmatrix}. \end{aligned}$$

Detailed stability analysis can be found in [8.45].

8.7.5 Summary

Since the computed-torque control suffers from parametric uncertainty, a variety of adaptive control schemes have been proposed. Firstly, we have presented an adaptive control scheme based on computed-torque control. Then, in order to overcome the mentioned drawbacks such as the measurability of the joint acceleration and the invertibility of the estimated inertia matrix, we presented an alternative adaptive control scheme that is free of these drawbacks. Recently, to incorporate a physics viewpoint into control, adaptive passivity-based control has become popular, and hence is introduced and discussed here. Finally, to reduce the computational load of the adaptive schemes, we presented an adaptive control with desired compensation.

Further Reading

A computationally very fast scheme dealing with adaptive control of rigid manipulators was presented in [8.46]. The stability analysis was completed by assuming that the joint dynamics are decoupled, i.e., that each joint is considered as an independent second-order linear system. A decentralized high-order adaptive variable-structure control is discussed in [8.47], the proposed scheme makes both position and velocity tracking errors of robot manipulators globally converge to zero asymptotically while allowing all signals in closed-loop systems to be bounded without the information of manipulator parameters. Other pioneering works in the field can be found, for example, in [8.48, 49]; although none of the fundamental dynamic model properties are used, the complete dynamics are taken into account, but the control input is discontinuous and may lead to chattering. Positive definiteness of the inertia matrix is explicitly used in [8.50], although it was assumed that some time-varying quantities remain constant during the adaptation. It is interesting to note that all of these schemes were based on the concept of model reference adaptive control (MRAC) developed in [8.51] for linear systems. Therefore, they are conceptually very different from the truly nonlinear schemes presented in this section.

A passive-based modified version of the least-squares estimation scheme has been proposed in [8.52] and [8.53], which guaranteed closed-loop stability of the scheme. Other schemes can be found in [8.54], where no use is made of the skew-symmetry property, and in [8.55], where the recursive Newton–Euler formulations is used instead of the Lagrange formulation to derive the manipulator dynamics, and thus computation is simplified to facilitate practical implementation.

Even though adaptive control provides a solution to the problem of parametric uncertainty, the robustness

of adaptive controllers remains a topic of great interest in the field. Indeed, measurement noise or unmodeled dynamics (e.g., flexibility) may result in unbounded closed-loop signals. In particular, the estimated parameters may diverge; this is a well-known phenomenon in adaptive control and is called parameter drift. Solutions inspired from the adaptive control of linear systems have been studied [8.56, 57], where a modified estimation ensures boundedness of the estimates. In [8.58], the controller in [8.32] is modified to enhance robustness.

8.8 Optimal and Robust Control

Given a nonlinear system, such as robotic manipulators, one can develop many stabilizing controls [8.29, 41]. In other words, the stability of the control system cannot determine a unique controller. It is natural that one seeks an optimal controller among the many stable ones. However, the design of an optimal controller is possible provided that a rather exact information on the target system is available, such as an exact system model [8.34, 59]. In the presence of discrepancy between the real system and its mathematical model, a designed optimal controller is no longer optimal, and may even end up being instable in the actual system. Generally speaking, the optimal control design framework is not the best one to deal with system uncertainty. To handle system uncertainty from the control design stage, a robust control design framework is necessary [8.60]. One of main objectives of robust control is to keep the controlled system stable even in presence of uncertainties in the mathematical model, unmodeled dynamics, and the like.

Let us consider an affine nonlinear system described by nonlinear time-varying differential equation in the state $\mathbf{x} = (x_1, x_2, \dots, x_n)^T \in \mathbb{R}^n$

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}, t) + \mathbf{G}(\mathbf{x}, t)\mathbf{u} + \mathbf{P}(\mathbf{x}, t)\mathbf{w}, \quad (8.103)$$

where $\mathbf{u} \in \mathbb{R}^m$ is the control input, and $\mathbf{w} \in \mathbb{R}^w$ is the disturbance. Without disturbances or unmodeled dynamics, the system simplifies to

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}, t) + \mathbf{G}(\mathbf{x}, t)\mathbf{u}. \quad (8.104)$$

Actually, there are many kinds of methods describing the nonlinear system according to the objective of control [8.1, 16, 21, 23, 34, 54].

8.8.1 Quadratic Optimal Control

Every optimal controller is based on its own cost function [8.61, 62]. One can define a cost function as [8.63,

64]

$$z = \mathbf{H}(\mathbf{x}, t)\mathbf{x} + \mathbf{K}(\mathbf{x}, t)\mathbf{u},$$

such that $\mathbf{H}^T(\mathbf{x}, t)\mathbf{K}(\mathbf{x}, t) = \mathbf{0}$, $\mathbf{K}^T(\mathbf{x}, t)\mathbf{K}(\mathbf{x}, t) = \mathbf{R}(\mathbf{x}, t) > \mathbf{0}$, and $\mathbf{H}^T(\mathbf{x}, t)\mathbf{H}(\mathbf{x}, t) = \mathbf{Q}(\mathbf{x}, t) > \mathbf{0}$. Then, we have

$$\frac{1}{2}\mathbf{z}^T\mathbf{z} = \frac{1}{2}\mathbf{x}^T\mathbf{Q}(\mathbf{x}, t)\mathbf{x} + \frac{1}{2}\mathbf{u}^T\mathbf{R}(\mathbf{x}, t)\mathbf{u}.$$

The quadratic optimal control for the system (8.104) is found by solving, for a first order differentiable positive-definite function $V(\mathbf{x}, t)$, the Hamilton–Jacobi–Bellman (HJB) equation [8.34, 59]

$$\begin{aligned} 0 = \text{HJB}(\mathbf{x}, t; V) &= V_t(\mathbf{x}, t) + \mathbf{V}_x(\mathbf{x}, t)\mathbf{f}(\mathbf{x}, t) \\ &\quad - \frac{1}{2}\mathbf{V}_x(\mathbf{x}, t)\mathbf{G}(\mathbf{x}, t)\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^T(\mathbf{x}, t)\mathbf{V}_x^T(\mathbf{x}, t) \\ &\quad + \frac{1}{2}\mathbf{Q}(\mathbf{x}, t), \end{aligned}$$

where $V_t = \frac{\partial V}{\partial t}$ and $\mathbf{V}_x = \frac{\partial V}{\partial \mathbf{x}^T}$. Then the quadratic optimal control is defined by

$$\mathbf{u} = -\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^T(\mathbf{x}, t)\mathbf{V}_x^T(\mathbf{x}, t). \quad (8.105)$$

Note that the HJB equation is a nonlinear second-order partial differential equation in $V(\mathbf{x}, t)$.

Unlike the aforementioned optimal control problem, the so-called inverse quadratic optimal control problem is to find a set of $\mathbf{Q}(\mathbf{x}, t)$ and $\mathbf{R}(\mathbf{x}, t)$ for which the HJB equation has a solution $V(\mathbf{x}, t)$. Then the inverse quadratic optimal control is defined by (8.105).

8.8.2 Nonlinear \mathcal{H}_∞ Control

When disturbances are not negligible, one can deal with their effect such that

$$\int_0^t \mathbf{z}^T(\mathbf{x}, \tau)\mathbf{z}(\mathbf{x}, \tau) d\tau \leq \gamma^2 \int_0^t \mathbf{w}^T\mathbf{w} d\tau, \quad (8.106)$$

where $\gamma > 0$ specifies the L_2 -gain of the closed-loop system from the disturbance input w to the cost variable z . This is called the L_2 -gain attenuation requirement [8.63–65]. One systematic way to design an optimal and robust control is given by the nonlinear \mathcal{H}_∞ optimal control. Let $\gamma > 0$ be given, by solving the following equation

$$\begin{aligned} \text{HJI}_\gamma(\mathbf{x}, t; V) &= V_t(\mathbf{x}, t) + \mathbf{V}_x(\mathbf{x}, t)\mathbf{f}(\mathbf{x}, t) \\ &\quad - \frac{1}{2}\mathbf{V}_x(\mathbf{x}, t)\{\mathbf{G}(\mathbf{x}, t)\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^T(\mathbf{x}, t) \\ &\quad - \gamma^{-2}\mathbf{P}(\mathbf{x}, t)\mathbf{P}^T(\mathbf{x}, t)\}\mathbf{V}_x^T(\mathbf{x}, t) \\ &\quad + \frac{1}{2}\mathbf{Q}(\mathbf{x}, t) \leq 0, \end{aligned} \quad (8.107)$$

then the control is defined by

$$\mathbf{u} = -\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^T(\mathbf{x}, t)\mathbf{V}_x^T(\mathbf{x}, t). \quad (8.108)$$

The partial differential inequality (8.107) is called the Hamilton–Jacobi–Isaac (HJI) inequality. Then one can define the inverse nonlinear \mathcal{H}_∞ optimal control problem that finds a set of $\mathbf{Q}(\mathbf{x}, t)$ and $\mathbf{R}(\mathbf{x}, t)$ such that the L_2 -gain requirement is achieved for a prescribed L_2 -gain γ [8.66].

Two things deserve further comment. The first is that the L_2 -gain requirement is only valid for disturbance signals w whose L_2 -norm is bounded. The second is that \mathcal{H}_∞ optimal control is not uniquely defined. Hence, one can choose a quadratic optimal among many \mathcal{H}_∞ optimal controllers. Precisely speaking, the control (8.108) should be called \mathcal{H}_∞ suboptimal control, since the desired L_2 -gain is prescribed a priori. A true \mathcal{H}_∞ optimal control is to find a minimal value of γ , such that the L_2 -gain requirement is achieved.

8.8.3 Passivity-Based Design of Nonlinear \mathcal{H}_∞ Control

There are many methodologies for the design of optimal and/or robust controls. Among these, passivity-based controls can take full advantage of the properties described above [8.31]. They consist of two parts: one coming from the reference motion compensation while preserving the passivity of the system, and the other to achieve stability, robustness, and/or optimality [8.66, 67].

Let us suppose that the dynamic parameters are identified as $\hat{\mathbf{H}}(\mathbf{q})$, $\hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})$, and $\hat{\boldsymbol{\tau}}_g(\mathbf{q})$, whose counterparts are $\mathbf{H}(\mathbf{q})$, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$, and $\boldsymbol{\tau}_g(\mathbf{q})$, respectively. Then, passivity-based control generates the following tracking control laws

$$\boldsymbol{\tau} = \hat{\mathbf{H}}(\mathbf{q})\ddot{\mathbf{q}}_{\text{ref}} + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}_{\text{ref}} + \hat{\boldsymbol{\tau}}_g(\mathbf{q}) - \mathbf{u}, \quad (8.109)$$

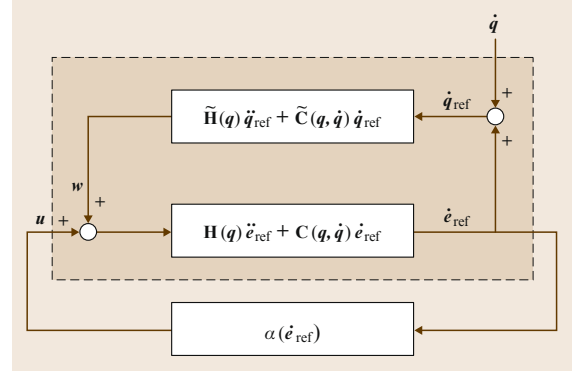

Fig. 8.7 The closed-loop system according to (8.111)

where $\ddot{\mathbf{q}}_{\text{ref}}$ is the reference acceleration defined by

$$\ddot{\mathbf{q}}_{\text{ref}} = \ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \quad (8.110)$$

where $\mathbf{K}_V = \text{diag}\{k_{V,i}\} > 0$ and $\mathbf{K}_P = \text{diag}\{k_{P,i}\} > 0$. Two parameters are involved in generating the reference acceleration. Sometimes the following alternative method can be adopted

$$\ddot{\mathbf{q}}_{\text{ref}} = \ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q.$$

This reduces the order of the closed-loop system because the state $\mathbf{x} = (\mathbf{e}_q^T, \dot{\mathbf{e}}_q^T)^T$ is sufficient for the system description, while the definition of (8.110) requires the state $\mathbf{x} = (\int \mathbf{e}_q^T, \mathbf{e}_q^T, \dot{\mathbf{e}}_q^T)^T$.

In Fig. 8.7, the closed-loop dynamics under the control is given by

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{e}}_{\text{ref}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{e}}_{\text{ref}} = \mathbf{u} + w, \quad (8.111)$$

where

$$\begin{aligned} \ddot{\mathbf{e}}_{\text{ref}} &= \ddot{\mathbf{e}}_q + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \\ \dot{\mathbf{e}}_{\text{ref}} &= \dot{\mathbf{e}}_q + \mathbf{K}_V \mathbf{e}_q + \mathbf{K}_P \int \mathbf{e}_q. \end{aligned}$$

If $d(t) = 0$ and $\hat{\mathbf{H}} = \mathbf{H}$, $\hat{\mathbf{C}} = \mathbf{C}$, $\hat{\boldsymbol{\tau}}_g = \boldsymbol{\tau}_g$, then $w = 0$. Otherwise, the disturbance is defined as

$$w = \tilde{\mathbf{H}}(\mathbf{q})\ddot{\mathbf{q}}_{\text{ref}} + \tilde{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}_{\text{ref}} + \tilde{\boldsymbol{\tau}}_g(\mathbf{q}) + d(t), \quad (8.112)$$

where $\tilde{\mathbf{H}} = \mathbf{H} - \hat{\mathbf{H}}$, $\tilde{\mathbf{C}} = \mathbf{C} - \hat{\mathbf{C}}$, and $\tilde{\boldsymbol{\tau}}_g = \boldsymbol{\tau}_g - \hat{\boldsymbol{\tau}}_g$. It is of particular interest that the system (8.111) defines a passive mapping between $\mathbf{u} + w$ and $\dot{\mathbf{e}}_{\text{ref}}$.

According to the manner in which the auxiliary control input \mathbf{u} is specified, passivity-based control can achieve stability, robustness, and/or optimality (Fig. 8.7).

8.8.4 A Solution to Inverse Nonlinear \mathcal{H}_∞ Control

Let us define the auxiliary control input by the reference-error feedback

$$\mathbf{u} = -\alpha \mathbf{R}^{-1}(\mathbf{x}, t) \dot{\mathbf{e}}_{\text{ref}}, \quad (8.113)$$

where $\alpha > 1$ is arbitrary. Then, the control provides the inverse nonlinear \mathcal{H}_∞ optimality.

Theorem 8.1 Inverse Nonlinear \mathcal{H}_∞ Optimality [8.66]

Let the reference acceleration generation gain matrices \mathbf{K}_V and \mathbf{K}_P satisfy

$$\mathbf{K}_V^2 > 2\mathbf{K}_P. \quad (8.114)$$

Then for a given $\gamma > 0$, the reference error feedback

$$\mathbf{u} = -\mathbf{K} \dot{\mathbf{e}}_{\text{ref}} = -\mathbf{K} \left(\dot{\mathbf{e}}_q + \mathbf{K}_V \mathbf{e}_q + \mathbf{K}_P \int \mathbf{e}_q \right) \quad (8.115)$$

satisfies the L_2 -gain attenuation requirement for

$$\mathbf{Q} = \begin{pmatrix} \mathbf{K}_P^2 \mathbf{K}_\gamma & 0 & 0 \\ 0 & (\mathbf{K}_V^2 - 2\mathbf{K}_P) \mathbf{K}_\gamma & 0 \\ 0 & 0 & \mathbf{K}_\gamma \end{pmatrix}, \quad (8.116)$$

$$\mathbf{R} = \mathbf{K}^{-1}, \quad (8.117)$$

provided that

$$\mathbf{K}_\gamma = \mathbf{K} - \frac{1}{\gamma^2} \mathbf{I} > 0. \quad (8.118)$$

Given γ , one can set $\mathbf{K} = \alpha \frac{1}{\gamma^2} \mathbf{I}$ for $\alpha > 1$. This yields $\mathbf{K}_\gamma = (\alpha - 1) \frac{1}{\gamma^2} \mathbf{I}$.

When the inertia matrix is identified as a diagonal constant matrix such as $\hat{\mathbf{H}} = \text{diag}\{\hat{m}_i\}$, one should set $\hat{\mathbf{C}} = \mathbf{0}$. In addition, one can set $\hat{\boldsymbol{\tau}}_g = \mathbf{0}$. Then this results in a decoupled PID control of the form

$$\tau_i = \hat{m}_i (\ddot{q}_{d,i} + k_{V,i} \dot{e}_{q,i} + k_{P,i} e_{q,i}) + \alpha \frac{1}{\gamma^2} \left(\dot{e}_{q,i} + k_{V,i} e_{q,i} + k_{P,i} \int e_{q,i} \right)$$

for $\alpha > 1$, which can be rewritten as

$$\begin{aligned} \tau_i = & \hat{m}_i \ddot{q}_{d,i} + \left(\hat{m}_i k_{V,i} + \alpha \frac{1}{\gamma^2} \right) \dot{e}_{q,i} \\ & + \left(\hat{m}_i k_{P,i} + \alpha \frac{k_{V,i}}{\gamma^2} \right) e_{q,i} + \alpha \frac{k_{P,i}}{\gamma^2} \int e_{q,i}. \end{aligned} \quad (8.119)$$

This leads to a PID control with the desired acceleration feedforward [8.68] given by

$$\tau_i = \hat{m}_i \ddot{q}_{d,i} + k_{V,i}^* \dot{e}_{q,i} + k_{P,i}^* e_{q,i} + k_{I,i}^* \int e_{q,i}, \quad (8.120a)$$

where

$$k_{V,i}^* = \hat{m}_i k_{V,i} + \alpha \frac{1}{\gamma^2}, \quad (8.120b)$$

$$k_{P,i}^* = \hat{m}_i k_{P,i} + \alpha \frac{k_{V,i}}{\gamma^2}, \quad (8.120c)$$

$$k_{I,i}^* = \alpha \frac{k_{P,i}}{\gamma^2}. \quad (8.120d)$$

8.9 Trajectory Generation and Planning

This section deals with the problem of *reference trajectory generation*, that is, the computation of desired position, velocity, acceleration and/or force/torque signals that are used as input values for the robot motion controllers introduced in Sects 8.3–8.8.

8.9.1 Geometric Paths and Trajectories

Path Planning

A path is a geometric representation of a plan to move from a start to a target pose. The task of planning is to find a collision-free path among a collection of

static and dynamic obstacles. Path planning can also include the consideration of dynamic constraints such as workspace boundaries, maximum velocities, maximum accelerations, and maximum jerks. We distinguish between *online* and *offline* path planning algorithms. Offline planned paths are static and calculated prior to execution. Online methods require algorithms that meet real-time constraints (i. e., algorithms that do not exceed a determinable worst-case computation time) to enable path (re-)calculations and/or adaptations during the robot motions in order to react to and interact with dynamic environments. This means that a robot

moves along a path that has not necessarily been computed completely, and which may change during the movement. Details about path planning concepts are described in Chap. 7, in Parts D and E, and specifically in Chap. 47.

Trajectory Planning

A trajectory is more than a path: It also includes velocities, accelerations, and/or jerks along a path (VIDEO 760). A common method is computing trajectories for a priori specified paths, which fulfill a certain criterion (e.g., minimum execution time). We distinguish between *online* and *offline* trajectory planning methods. An offline calculated trajectory cannot be influenced during its execution, while online trajectory planning methods can (re-)calculate and/or adapt robot motions behavior during the movement. The reasons for this (re-)calculation and/or adaptation can vary: improvement of accuracy, better utilization of currently available dynamics, reaction to and interaction with a dynamic environment, or reaction to (sensor) events. Besides the distinction between online and offline methods, we can further distinguish between (1) one-dimensional (1-D) and multi-dimensional trajectories and (2) single-point and multi-point trajectories. Multi-point trajectories typically relate to a path.

8.9.2 Joint Space and Operational Space Trajectories

Depending on the control state space, trajectory generators provide set points for tracking controllers in joint space or in operational space. In either space, a trajectory can be represented in several different ways: cubic splines, quintic splines, higher-order splines, harmonics (sinusoidal functions), exponential functions, Fourier series, and more.

Joint Space Trajectories

Consider the torque control input (8.29)

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})\mathbf{v} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}),$$

and the PD controller (8.30)

$$\mathbf{v} = \ddot{\mathbf{q}}_d + \mathbf{K}_V(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}), \quad (8.121)$$

or PID controller (8.31), respectively, the task of a trajectory generator in joint space coordinates is computing the signals $\mathbf{q}_d(t)$, $\dot{\mathbf{q}}_d(t)$, and $\ddot{\mathbf{q}}_d(t)$. These three signals contain the reference trajectory and are used as input values for the tracking controller.

During nominal operation the joint torques required to execute a trajectory should not exceed joint

force/torque limits $\boldsymbol{\tau}_{\min}(t)$ and $\boldsymbol{\tau}_{\max}(t)$,

$$\boldsymbol{\tau}_{\min}(t) \leq \boldsymbol{\tau}(t) \leq \boldsymbol{\tau}_{\max}(t) \quad \forall t \in \mathbb{R}. \quad (8.122)$$

Operational Space Trajectories

Similarly to (8.29), we can also consider trajectories represented by \mathbf{x}_d , $\dot{\mathbf{x}}_d$, and $\ddot{\mathbf{x}}_d$ for an operational space controller (8.9)

$$\mathbf{f}_c = \boldsymbol{\Lambda}(\mathbf{q})\boldsymbol{\mu} + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \boldsymbol{\eta}(\mathbf{q}),$$

with a PD control law of

$$\boldsymbol{\mu} = \ddot{\mathbf{x}}_d + \mathbf{K}_V(\dot{\mathbf{x}}_d - \dot{\mathbf{x}}) + \mathbf{K}_P(\mathbf{x}_d - \mathbf{x}). \quad (8.123)$$

With the transformation into joint space using the inverse of (8.8), the operational space trajectory generator must assure that the limits given in (8.122) are not violated. It is the responsibility of the path planner (Chap. 7) that all points along the trajectory are in the robot workspace and that start and goal poses can be reached in the same joint configuration. It is the responsibility of the trajectory planner that joint torque and velocity constraints are not violated even in the presence of kinematic singularities.

8.9.3 Trajectory Representations

Mathematical Representations

Functions for $\ddot{\mathbf{q}}_d(t)$ (8.121) and $\ddot{\mathbf{x}}_d$ (8.123) can be represented in several ways that are described here.

Polynomial Trajectories. One of the simplest ways to represent a robot trajectory is a polynomial function of degree m for each joint $i \in \{1, \dots, n\}$

$$q_i(t) = a_{i,0} + a_{i,1}t + a_{i,2}t^2 + \dots + a_{i,m}t^m, \quad (8.124)$$

so that $\mathbf{q}(t)$ can be composed (or $\mathbf{x}(t)$ in operational space, respectively). In the simplest case, cubic polynomials are used, which, however, leads to non-steady acceleration signals with infinite jerks. Quintic and higher-order polynomials allow for steady acceleration signals as well as arbitrary position, velocity, and acceleration vectors and the beginning and at the end of the trajectory. To determine the coefficients $a_{i,j} \quad \forall (i, j) \in \{1, \dots, n\} \times \{0, \dots, m\}$ of (8.124), the execution time t_{trgt} , at which the target state will be reached needs to be known. The left part of Fig. 8.8a shows a quintic trajectory for three DOFs starting at $t_0 = 0$ s with an execution time of $t_{\text{trgt}} = 2.5$ s. To connect a trajectory segment to preceding and succeeding segments, the fol-

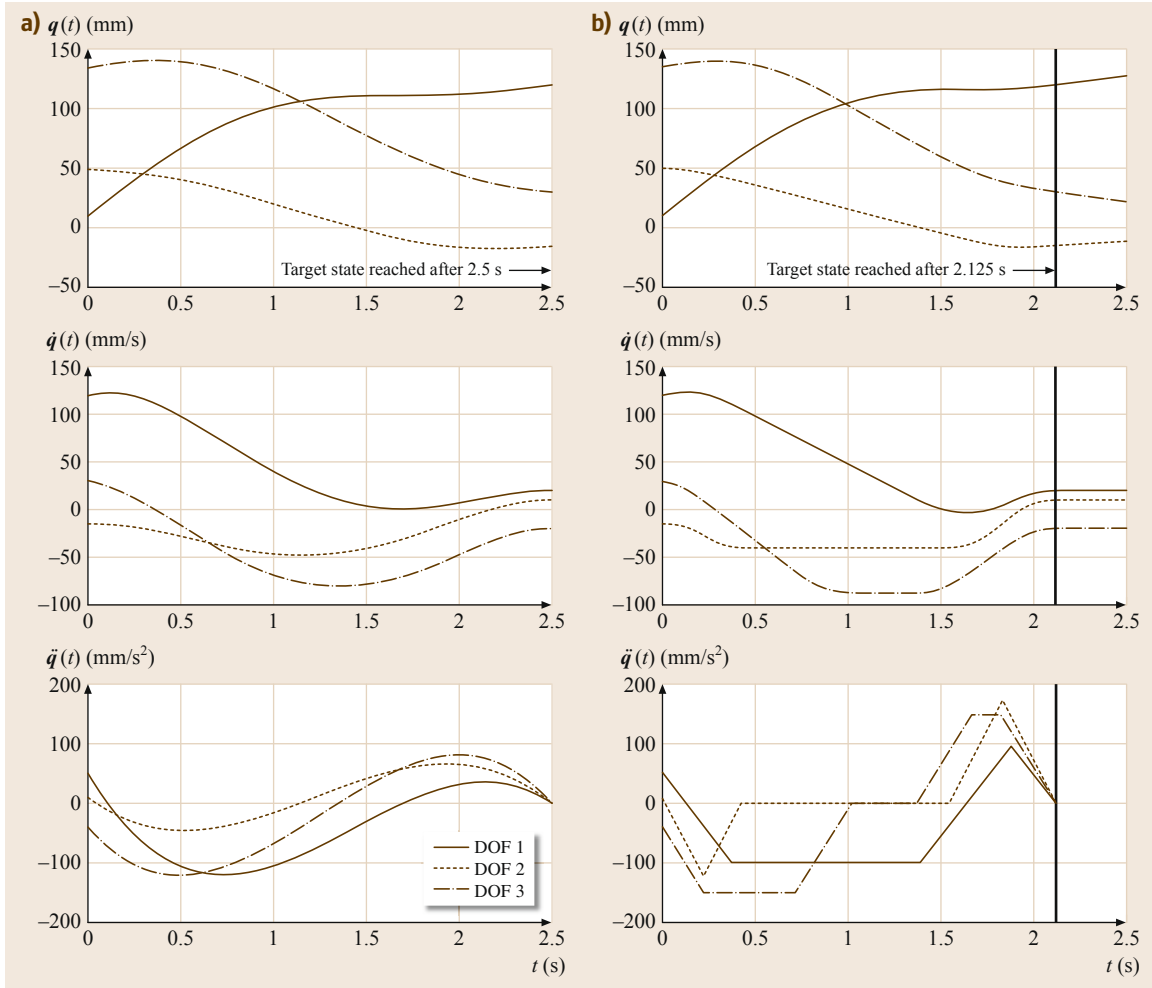

Fig. 8.8a,b Two sample trajectories for a three-DOF robot ($n = 3$). The trajectory in (a) is represented by quintic splines, and the trajectory in (b) by piecewise polynomials

lowing six constraints need to be satisfied for all n joints

$$\begin{aligned}
 q_i(t_0) &= q_{i,\text{start}} = a_{i,0} \\
 q_i(t_{\text{trgt}}) &= q_{i,\text{trgt}} = a_{i,0} + a_{i,1}t_{\text{trgt}} + a_{i,2}t_{\text{trgt}}^2 \\
 &\quad + a_{i,3}t_{\text{trgt}}^3 + a_{i,4}t_{\text{trgt}}^4 + a_{i,5}t_{\text{trgt}}^5 \\
 \dot{q}_i(t_0) &= \dot{q}_{i,0} = a_{i,1} \\
 \dot{q}_i(t_{\text{trgt}}) &= \dot{q}_{i,\text{trgt}} = a_{i,1} + 2a_{i,2}t_{\text{trgt}} + 3a_{i,3}t_{\text{trgt}}^2 \\
 &\quad + 4a_{i,4}t_{\text{trgt}}^3 + 5a_{i,5}t_{\text{trgt}}^4 \\
 \ddot{q}_i(t_0) &= \ddot{q}_{i,0} = 2a_{i,2} \\
 \ddot{q}_i(t_{\text{trgt}}) &= \ddot{q}_{i,\text{trgt}} = 2a_{i,2} + 6a_{i,3}t_{\text{trgt}} + 12a_{i,4}t_{\text{trgt}}^2 \\
 &\quad + 20a_{i,5}t_{\text{trgt}}^3.
 \end{aligned}$$

A unique closed-form solution can be computed, so that all polynomial coefficients $a_{i,j} \forall (i, j) \in$

$\{1, \dots, n\} \times \{0, \dots, 5\}$ can be determined for one trajectory segment.

Piecewise Polynomials. Polynomials of different degrees can be concatenated to represent a trajectory between an initial state $(q_0, \dot{q}_0, \ddot{q}_0)$ and a target state $(q_{\text{trgt}}, \dot{q}_{\text{trgt}}, \ddot{q}_{\text{trgt}})$. For instance, the classical double-S velocity profile [8.69] with trapezoidal acceleration and deceleration profiles and a cruise-velocity segment in the middle consists of seven polynomials of degrees 3-2-3-1-3-2-3 (m in (8.124)). The right part of Fig. 8.8 shows a trajectory represented by piecewise polynomials. To compute time-optimal trajectories under purely kinematic constraints (e.g., $\dot{q}_{\text{max}}, \ddot{q}_{\text{max}}, \ddot{q}_{\text{min}}$, etc.), piecewise polynomials are used, because they allow always using one signal at its kinematic limit (Fig. 8.8b and [8.70]).

Trigonometric Trajectories. Similarly to (8.124), trigonometric functions can be used to represent harmonic, cycloidal, and elliptic trajectories [8.71, 72]. A simple example for a harmonic trajectory for one joint i is

$$q_i(t) = \frac{q_{i,\text{trgt}} - q_{i,0}}{2} \left(1 - \cos \frac{\pi (t - t_0)}{t_{\text{trgt}} - t_0} \right) + q_{i,0} . \quad (8.125)$$

While any order of derivatives of trigonometric functions is continuous, they might be discontinuous at t_0 and t_{trgt} .

Other Representations. *Exponential Trajectories* and *Fourier Series Expansions* [8.72] are particularly suited to minimize natural vibrations on robot mechanisms introduced by reference trajectories.

Trajectories and Paths

To draw the connection to Chap. 7 and Parts D and E, trajectories and paths are often tightly coupled.

Trajectories Along Predefined Paths. A path in joint space can be described by a function $\mathbf{q}(s(t))$ with $s \in [t_0, t_{\text{trgt}}]$, where the start configuration of the path is $\mathbf{q}(t_0)$ and the target configuration is $\mathbf{q}(t_{\text{trgt}})$. To move a robot along the path, an appropriate function $s(t)$ needs to be computed that does not violate any of the kinematic and dynamic constraints [8.73–75]. If a path is given in operational space, $\mathbf{x}(s(t))$ can be mapped to $\mathbf{q}(t)$ (Sect. 8.2).

Multi-Dimensional Trajectories. Instead of using a one-dimensional function $s(t)$ to parameterize a path segment, trajectories can also be described by individual functions for each DOF i to represent $\mathbf{q}(s(t))$ or $\mathbf{x}(s(t))$, respectively. To connect two arbitrary states, the signals for each individual degree of freedom need to be time-synchronized [8.70], so that all DOFs reach their target state of motion at the very same instant. Those trajectories may also be phase-synchronized [8.76], so that the trajectories of all DOFs are derived from a one master DOF and only scaled by a factor to achieve homothety [8.77]. The two trajectories in Fig. 8.8 are time-synchronized but not phase-synchronized.

Multi-Point Trajectories. If instead of an entirely defined geometric path or a motion to a single way point, an entire series of geometric way points is given, the trajectory that connects all way points in a given state space needs to be computed. Trajectory segments between two way points can be represented with any of

the above mentioned representations as long as the position signal and its derivatives up an appropriate order are continuous (at least C^1 continuous). Splines, B-splines, or Bezier splines are used to generate either a reference trajectory or a geometric path, which then can be parameterized with a function $s(t)$.

8.9.4 Trajectory Planning Algorithms

The following part provides an overview of online and offline trajectory planning concepts.

Constraints

Constraints for trajectory planners can manifold:

- **Kinematic:** maximum velocities, accelerations, jerks, etc. and workspace space limits
- **Dynamic:** maximum joint or actuator forces and/or torques
- **Geometric:** no collisions with static and dynamic objects in the workspace
- **Temporal:** reaching a state within a given time interval or at a given time.

These and other constraints may have to be taken into account at the same time. Depending on the robot and the task, additional optimization criteria may be considered (e.g., time-optimality, minimum-jerk, maximum distance to workspace boundaries, minimum energy).

Offline Trajectory Planning

Kahn and Roth [8.78] showed results using optimal, linear control theory to achieve a near-time-optimal solution for linearized manipulators. The resulting trajectories are jerk-limited and lead to smaller trajectory-following errors and to less excitation of structural natural frequencies in the system.

The work of *Brady* [8.79] introduced several techniques of trajectory planning in joint space and *Paul* [8.80] and *Taylor* [8.81] published works about the planning of trajectories in Cartesian space in parallel to Brady. *Lin et al.* [8.82] published another purely kinematic approach as did *Castain and Paul* [8.69].

Hollerbach [8.83] first introduced the consideration of the nonlinear inverse robot dynamics for the generation of manipulator trajectories.

During the middle of the 1980s, three groups developed techniques for time-optimal trajectory planning for arbitrarily specified paths: *Bobrow* [8.73], *Shin and McKay* [8.74], and *Pfeiffer and Johanni* [8.75]. Trajectories are composed of three curves: the maximum acceleration curve, the maximum velocity curve, and

the maximum deceleration curve. The proposed algorithms find the intersection points of these three curves.

These algorithms have become the fundament for many follow-up works: *Kyriakopoulos and Sridis* [8.84] added minimum-jerk criteria; *Slotine and Yang* abandoned the computationally expensive calculation of the maximum velocity curve [8.85]; *Shiller and Lu* added methods for handling dynamic singularities [8.86]; *Fiorini and Shiller* extended the algorithm for known dynamic environments with moving obstacles [8.87].

Online Trajectory Planning

An online modification of a planned trajectory may have several reasons: (i) The trajectory becomes adapted in order to improve the accuracy with a path specified beforehand; (ii) The robotic system reacts on sensor signals and/or events that cannot be predicted beforehand, because the robot acts in a (partly) unknown and dynamic environment.

Improving Path Accuracy. All previously described off-line trajectory planning methods assume a dynamic model that describes the behavior of the real robot exactly. In practice, this is often not the case, and some robot parameters are only estimated, some dynamic effects remain unmodeled, and system parameters may change during operation. If this is the case, the resulting robot motion is not time-optimal anymore and/or the maximum actuator forces and/or torques are exceeded, which leads to an undesired difference between the specified and the executed path.

Dahl and Nielsen [8.88] extended [8.73–75] by adapting the acceleration along the path, so that the underlying trajectory-following controller becomes adapted depending on the current state of motion. The

approaches of *Cao et al.* [8.89, 90] use cubic splines to generate smooth paths in joint space with time-optimal trajectories. *Constantinescu and Croft* [8.91] suggest a further improvement to the approach of [8.86] with objective to limit the derivative of actuator forces/torques. *Macfarlane and Croft* extended this approach further by adding jerk limitations to quintic splines (Fig. 8.8) [8.92].

Sensor-Based Trajectory Adaptation

The last paragraph presented an overview of online trajectory generation methods for improving the path accuracy, while this one focuses on the online consideration of sensor signals, for instance, for the purpose of collision avoidance ( VIDEO 757,  VIDEO 758) or switching between controllers or control gains ( VIDEO 759,  VIDEO 761).

In 1988, *Andersson* presented an online trajectory planning for a Ping-Pong-playing PUMA 260 manipulator that computes parameterized quintic polynomials [8.93, 94]. Based on [8.73–75], *Lloyd and Hayward* proposed a technique to transition between two different trajectory segments [8.95] using a transition window [8.81]. *Ahn et al.* introduced a method to connect two arbitrary motion states online, which does not take into account kinematic or dynamic constraints [8.96]. *Broquère et al.*, *Haschke et al.*, and *Kröger* extended this approach for multi-dimensional trajectories, so that kinematic constraints are taken into account [8.70, 97, 98].

Further Reading

Overviews of the domain of robot reference trajectory generation can be found in the textbooks of *Biagiotti and Melchiorri* [8.72], *Craig* [8.99], *Fu et al.* [8.100], and *Spong et al.* [8.101].

8.10 Digital Implementation

Most controllers introduced in the previous sections are digitally implemented on microprocessors. In this section basic but essential practical issues related to their computer implementation are discussed. When the controller is implemented on a computer control system, the analog inputs are read and the outputs are set with a certain sampling period. This is a drawback compared to analog implementations, since sampling introduces time delays into the control loop. Figure 8.9 shows the overall block diagram of control system with a boxed digital implementation part. When a digital computer is used to implement a control law, it is convenient to di-

vide coding sequence in the interrupt routine into four process routines, as shown in Fig. 8.10. Reading the input signal from sensors and writing the control signal to digital-to-analog (D/A) converters synchronized at the correct frequency is very important. Therefore, these processes are located in the first routine. After saving counter values and extracting D/A values, which are already calculated one step before, the next routine produces reference values. Control routines with filters follow and produce scalar or vector control outputs. Finally, the user interface for checking parameter values is made and will be used for tuning and debugging.

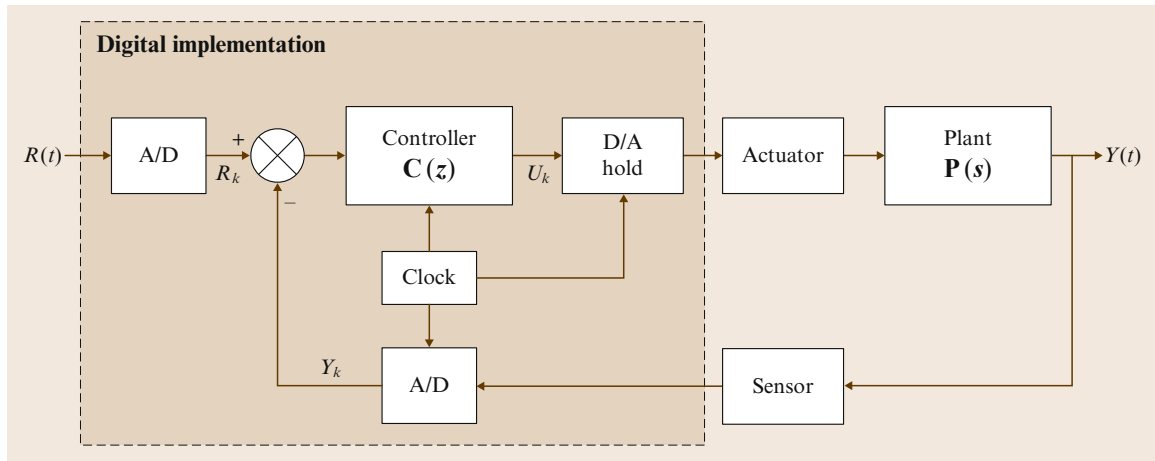

Fig. 8.9 Digital implementation of system control

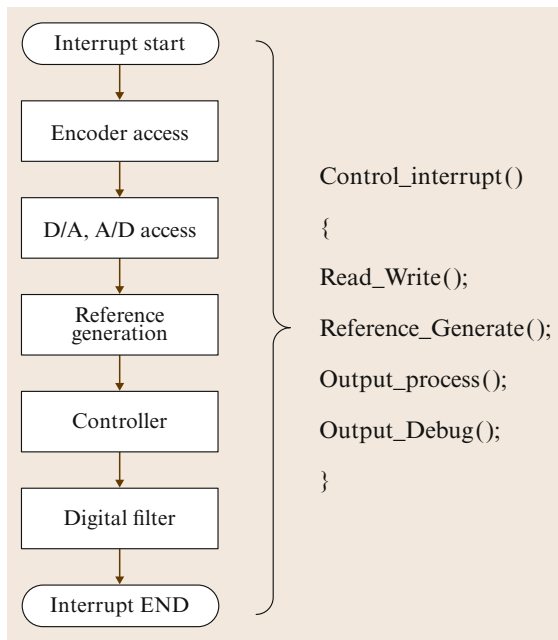

Fig. 8.10 The sequence in the interrupt routine for digital control

8.10.1 Z-Transform for Motion Control Implementation

Continuous-time systems are transformed into discrete-time systems by using the Z-transform. A discrete-time system is used to obtain a mathematical model that gives the behavior of a physical process at the sampling points, although the physical process is still a continuous-time system. A Laplace transform is used for the analysis of control system in the s -domain. In most cases, the design of controllers and filters are done

using tools in the s -domain. In order to realize those results in program code, understanding the Z-transform is essential. All controllers and filters designed in the s -domain can be easily translated to a program code through a Z-transform because it has the form of digitized difference sequences.

A PID controller is used as an example. In transfer function form, this controller has the basic structure

$$\frac{Y(s)}{E(s)} = K_P + \frac{K_I}{s} + sK_V. \quad (8.126)$$

There are several methods for transformation from the frequency domain to the discrete domain. For stability conservation, backward Euler and Tustin algorithms are often used. Though the Tustin algorithm is known as the more exact one, the backward Euler algorithm is utilized in the following procedure.

After substituting the backward Euler equation into (8.126),

$$s \cong \frac{1 - z^{-1}}{T},$$

the following discrete form is produced

$$\frac{Y(z)}{E(z)} = \frac{\alpha + \beta z^{-1} + \gamma z^{-2}}{T(1 - z^{-1})}, \quad (8.127)$$

where

$$\begin{aligned} \alpha &= K_I T^2 + K_P T + K_V, \\ \beta &= -K_P T - 2K_V, \\ \gamma &= K_V. \end{aligned}$$

Sometimes a differentiator s in the PID controller makes the implementation infeasible when the mea-

surement noise is severe. One can remedy the controller (8.126) by attaching a lowpass filter with filter time constant σ

$$\frac{Y(s)}{E(s)} = K_P + \frac{K_I}{s} + \frac{s}{\sigma s + 1} K_V. \quad (8.128)$$

Again, substituting the backward Euler equation into (8.128) produces

$$\frac{Y(z)}{E(z)} = \frac{\alpha + \beta z^{-1} + \gamma z^{-2}}{1 - \delta z^{-1} - \psi z^{-2}}, \quad (8.129)$$

where

$$\begin{aligned} \alpha &= K_P + K_I T + \frac{K_V}{\sigma + T}, \\ \beta &= -\frac{(2\sigma + T)K_P + \sigma T K_I + 2K_V}{\sigma + T}, \\ \gamma &= \frac{\sigma K_P + K_V}{\sigma + T}, \\ \delta &= \frac{2\sigma + T}{\sigma + T}, \\ \psi &= -\frac{\sigma}{\sigma + T}, \end{aligned}$$

in which the filter time constant σ is determined from a cutoff frequency f_c [Hz] for removing noises such as $\sigma = \frac{1}{2\pi f_c}$.

8.10.2 Digital Control for Coding

Inverse Z-transform produces a difference equation for digital control. Furthermore the difference equation can be directly converted into the control program code. Since the inverse Z-transform of $Y(z)$ is y_k and z^{-1} implies the previous sample time, $z^{-1}Y(z) = y_{k-1}$ and $z^{-2}Y(z) = y_{k-2}$.

Now, the PID controller expressed by (8.127) is rearranged using the difference equation

$$\begin{aligned} T(y_k - y_{k-1}) &= \alpha e_k + \beta e_{k-1} + \gamma e_{k-2}, \\ y_k - y_{k-1} &= \frac{1}{T}(\alpha e_k + \beta e_{k-1} + \gamma e_{k-2}). \end{aligned} \quad (8.130)$$

For practical use, the PID controller can be directly coded in the program as follows

$$y_k = K_{P,c} e_k + K_{V,c} e_k^v + K_{I,c} e_k^i,$$

where

$$\begin{aligned} e_k &= p_{k,\text{desired}} - p_k, \\ e_k^v &= v_{k,\text{desired}} - v_k \\ &= (p_{k,\text{desired}} - p_{k-1,\text{desired}}) - (p_k - p_{k-1}) \end{aligned}$$

$$= e_k - e_{k-1},$$

$$e_k^i = e_{k-1}^i + e_k = \sum_{j=0}^k e_j,$$

in which p_k is the present position, v_k is the present velocity, desired means reference to be followed, and c means coded form for digital control. Now let us obtain the difference between the present control output and the previous one

$$\begin{aligned} y_k - y_{k-1} &= [K_{P,c} e_k - K_{P,c} e_{k-1}] \\ &\quad + [K_{V,c} (e_k - e_{k-1}) - K_{V,c} (e_{k-1} - e_{k-2})] \\ &\quad + [K_{I,c} e_k^i - K_{I,c} e_{k-1}^i] \\ &= (K_{P,c} + K_{V,c} + K_{I,c}) e_k \\ &\quad - (K_{P,c} + 2K_{V,c}) e_{k-1} + K_{V,c} e_{k-2}. \end{aligned} \quad (8.131)$$

Comparing the parameters in (8.130) and (8.131), one obtains

$$\begin{aligned} \frac{\alpha}{T} &= K_P + \frac{K_V}{T} + K_I T = (K_{P,c} + K_{V,c} + K_{I,c}), \\ \frac{\beta}{T} &= -K_P - \frac{2K_V}{T} = -(K_{P,c} + 2K_{V,c}), \\ \frac{\gamma}{T} &= \frac{K_V}{T} = K_{V,c}, \end{aligned}$$

which shows that there is a relation between the designed and coded forms of the gains

$$\begin{aligned} K_{P,c} &= K_P, \\ K_{V,c} &= \frac{K_V}{T}, \\ K_{I,c} &= K_I T. \end{aligned} \quad (8.132)$$

As the sampling frequency is increased in the same system, the coded K_V gain should be increased and the coded K_I gain should be decreased. Using this method, the designed controller can be coded in a digital signal processor (DSP) or microprocessor. However, sufficient analysis and simulation for control algorithms should be performed beforehand to obtain successful control system performance.

In addition, the PID controller with lowpass filter (8.129) can be implemented as

$$\begin{aligned} y_k - \delta y_{k-1} - \psi y_{k-2} &= \alpha e_k + \beta e_{k-1} + \gamma e_{k-2}, \\ y_k &= \delta y_{k-1} + \psi y_{k-2} + \alpha e_k + \beta e_{k-1} + \gamma e_{k-2}. \end{aligned} \quad (8.133)$$

Using the same procedures, one can arrive at the similar control program code for digital control.

PID Control Experiment (Multimedia)

According as the gains change, the performance variations of PID controller implemented in the digital

control system are shown in the multimedia source to help readers' understanding  VIDEO 25.

8.11 Learning Control

Since many robotic applications, such as pick-and-place operations, paintings, and circuit-board assembly, involve repetitive motions, it is natural to consider the use of data gathered in previous cycles to try to improve the performance of the manipulator in subsequent cycles. This is the basic idea of repetitive control or learning control. Consider the robot model given in Sect. 8.1 and suppose that one is given a desired joint trajectory $q_d(t)$ on a finite time interval $0 \leq t \leq T$. The reference trajectory q_d is used in repeated trails of the manipulator, assuming either that the trajectory is periodic, $q_d(T) = q_d(0)$, (repetitive control) or that the robot is reinitialized to lie on the desired trajectory at the beginning of each trail (learning control). Hereafter, we use the term learning control to mean either repetitive or learning control.

8.11.1 Pure P-Type Learning Control

Let τ_k be the input torque during the k -th cycle, which produces an output $q_k(t)$, $0 \leq t \leq T_{\text{bnd}}$. Now, let us consider the following set of assumptions:

- Assumption 1: Every trial ends at a fixed time of duration $T_{\text{bnd}} > 0$.
- Assumption 2: Repetition of the initial setting is satisfied.
- Assumption 3: Invariance of the system dynamics is ensured throughout these repeated trails.
- Assumption 4: Every output q_k can be measured and thus the error signal $\Delta q_k = q_k - q_d$ can be utilized in the construction of the next input τ_{k+1} .
- Assumption 5: The dynamics of the robot manipulators is invertible.

The learning control problem is to determine a recursive learning law L

$$\tau_{k+1} = L[\tau_k(t), \Delta q_k(t)], \quad 0 \leq t \leq T_{\text{bnd}}, \quad (8.134)$$

where $\Delta q_k(t) = q_k(t) - q_d(t)$, such that $\|\Delta q_k\| \rightarrow 0$ as $k \rightarrow \infty$ in some suitably defined function norm, $\|\cdot\|$. The initial control input can be any control input that produces a stable output, such as PD control. Such learning control schemes are attractive because accurate models of the dynamics need not be known a priori.

Several approaches have been used to generate a suitable learning law L and to prove convergence of

the output error. A pure P-type learning law is one of the form

$$\tau_{k+1}(t) = \tau_k(t) - \Phi \Delta q_k(t), \quad (8.135)$$

and is given this name because the correction term for the input torque at each iteration is proportional to the error Δq_k . Now let τ_d be defined by the computed-torque control, i. e.,

$$\begin{aligned} \tau_d(t) = & \mathbf{H}[q_d(t)]\ddot{q}_d(t) + \mathbf{C}[q_d(t), \dot{q}_d(t)]\dot{q}_d(t) \\ & + \tau_g[q_d(t)]. \end{aligned} \quad (8.136)$$

One should recall that the function τ_k actually does not need to be computed; it is sufficient to know that it exists. Considering the P-type learning control law, we have

$$\Delta \tau_{k+1}(t) = \Delta \tau_k(t) - \Phi \Delta q_k(t), \quad (8.137)$$

where $\Delta \tau_k(t) = \tau_k(t) - \tau_d(t)$, so that

$$\|\Delta \tau_{k+1}(t)\|^2 \leq \|\Delta \tau_k(t)\|^2 - \beta \|\Phi \Delta q_k(t)\|^2 \quad (8.138)$$

provided there exist positive constant λ and β such that

$$\int_0^{T_{\text{bnd}}} e^{-\lambda t} \Delta q_k^T \Delta \tau_k(t) dt \geq \frac{1+\beta}{2} \|\Phi \Delta q_k(t)\|^2 \quad (8.139)$$

for all k . It then follows from the inequality above that $\Delta q_k \rightarrow 0$ in the norm sense as $k \rightarrow \infty$. Detailed stability analysis of this control scheme is given in [8.102, 103].

8.11.2 P-Type Learning Control with a Forgetting Factor

Although pure P-type learning control achieves the desired goal, several strict assumptions may be not valid in actual implementations, for example, there may be an initial setting error. Furthermore, there may be small but

nonrepeatable fluctuations of dynamics. Finally, there may exist a (bounded) measurement noise ξ_k such that

$$\Delta q_k(t) + \xi_k(t) = [q_k(t) + \xi_k(t)] - q_d(t). \quad (8.140)$$

Thus the learning control scheme may fail. In order to enhance the robustness of P-type learning control, a forgetting factor is introduced in the form

$$\begin{aligned} \tau_{k+1}(t) = & (1 - \alpha)\tau_k(t) + \alpha\tau_0(t) \\ & - \Phi[\Delta q_k(t) + \xi_k(t)]. \end{aligned} \quad (8.141)$$

The original idea of using a forgetting factor in learning control originated with [8.104].

It has been rigorously proven that P-type learning control with a forgetting factor guarantees convergence to a neighborhood of the desired one of size $O(\alpha)$. Moreover, if the content of a long-term memory is refreshed after every k trials, where k is of $O(1/\alpha)$, then the trajectories converge to an ε -neighborhood of the

desired control goal. The size of ε is dependent on the magnitude of the initial setting error, the nonrepeatable fluctuations of the dynamics, and the measurement noise. For a detailed stability investigation, please refer to [8.105, 106].

8.11.3 Summary

By applying learning control, the performance of repetitive tasks (such as painting or pick-and-place operation) is improved by utilizing data gathered in the previous cycles. In this section, two learning control schemes were introduced. First, pure P-type learning control and its robustness problem were described. Then P-type learning control with a forgetting factor was presented, enhancing the robustness of learning control.

Further Reading

Rigorous and refined exploration of learning control is first discussed independently in [8.2, 12].

9. Force Control

Luigi Villani, Joris De Schutter

A fundamental requirement for the success of a manipulation task is the capability to handle the physical contact between a robot and the environment. Pure motion control turns out to be inadequate because the unavoidable modeling errors and uncertainties may cause a rise of the contact force, ultimately leading to an unstable behavior during the interaction, especially in the presence of rigid environments. Force feedback and force control becomes mandatory to achieve a robust and versatile behavior of a robotic system in poorly structured environments as well as safe and dependable operation in the presence of humans. This chapter starts from the analysis of *indirect force control* strategies, conceived to keep the contact forces limited by ensuring a suitable compliant behavior to the end effector, without requiring an accurate model of the environment. Then the problem of *interaction tasks* modeling is analyzed, considering both the case of a rigid environment and the case of a compliant environment. For the specification of an interaction task, natural constraints set by the task geometry and artificial constraints set by the control strategy are established, with respect to suitable task frames. This formulation is the essential premise to the synthesis of *hybrid force/motion control* schemes.

9.1 Background

Research on robot force control has flourished in the past three decades. Such a wide interest is motivated by the general desire of providing robotic systems with enhanced sensory capabilities. Robots using force, touch, distance, and visual feedback are expected to autonomously operate in unstructured environments other than the typical industrial shop floor.

Since the early work on telemanipulation, the use of force feedback was conceived to assist the human operator in the remote handling of objects with a slave manipulator. More recently, cooperative robot systems have been developed where two or more manipulators (viz. the fingers of a dexterous robot hand) are to be controlled so as to limit the exchanged forces

and avoid squeezing of a commonly held object. Force control plays a fundamental role also in the achievement of robust and versatile behavior of robotic systems in open-ended environments, providing intelligent response in unforeseen situations and enhancing human–robot interaction.

9.1.1 From Motion Control to Interaction Control

Control of the physical interaction between a robot manipulator and the environment is crucial for the successful execution of a number of practical tasks where the robot end-effector has to manipulate an object or perform some operation on a surface. Typical examples in industrial settings include polishing, deburring, machining or assembly. A complete classification of possible robot tasks, considering also nonindustrial applications, is practically infeasible in view of the large variety of cases that may occur, nor would such a classification be really useful to find a general strategy to control the interaction with the environment.

During contact, the environment may set constraints on the geometric paths that can be followed by the end-effector, denoted as *kinematic constraints*. This situation, corresponding to the contact with a stiff surface, is generally referred to as *constrained motion*. In other cases, the contact task is characterized by a dynamic interaction between the robot and the environment that can be inertial (as in pushing a block), dissipative (as in sliding on a surface with friction) or elastic (as in pushing against an elastically compliant wall). In all these cases, the use of a pure motion control strategy for controlling interaction is prone to failure, as explained below.

Successful execution of an interaction task with the environment by using motion control could be obtained only if the task were accurately planned. This would in turn require an accurate model of both the robot manipulator (kinematics and dynamics) and the environment (geometry and mechanical features). A manipulator model may be known with sufficient precision, but a detailed description of the environment is difficult to obtain.

To understand the importance of task planning accuracy, it is sufficient to observe that in order to perform a mechanical part mating with a positional approach the relative positioning of the parts should be guaranteed with an accuracy of an order of magnitude greater than part mechanical tolerance. Once the absolute position of one part is exactly known, the manipulator should guide the motion of the other with the same accuracy.

In practice, the planning errors may give rise to a contact force and moment, causing a deviation of the

end-effector from the desired trajectory. On the other hand, the control system reacts to reduce such deviations. This ultimately leads to a build-up of the contact force until saturation of the joint actuators is reached or breakage of the parts in contact occurs.

The higher the environment stiffness and position control accuracy are, the more easily a situation like the one just described can occur. This drawback can be overcome if a *compliant behavior* is ensured during the interaction. This compliant behavior can be achieved either in a passive or in an active fashion.

Passive Interaction Control

In passive interaction control the trajectory of the robot end-effector is modified by the interaction forces due to the inherent compliance of the robot. The compliance may be due to the structural compliance of the links, joints, and end-effector, or to the compliance of the position servo. Soft robot arms with elastic joints or links are purposely designed for intrinsically safe interaction with humans. In industrial applications, a mechanical device with passive compliance, known as the remote center of compliance (RCC) device [9.1], is widely adopted. An RCC is a compliant end-effector mounted on a rigid robot, designed and optimized for peg-into-hole assembly operations.

The passive approach to interaction control is very simple and cheap, because it does not require force/torque sensors; also, the preprogrammed trajectory of the end-effector must not be changed at execution time; moreover, the response of a passive compliance mechanism is much faster than active repositioning by a computer control algorithm. However, the use of passive compliance in industrial applications lacks flexibility, since for every robotic task a special-purpose compliant end-effector has to be designed and mounted. Also, it can only deal with small position and orientation deviations of the programmed trajectory. Finally, since no forces are measured, it can not guarantee that high contact forces will never occur.

Active Interaction Control

In active interaction control, the compliance of the robotic system is mainly ensured by a purposely designed control system. This approach usually requires the measurement of the contact force and moment, which are fed back to the controller and used to modify or even generate online the desired trajectory of the robot end-effector.

Active interaction control may overcome the aforementioned disadvantages of passive interaction control, but it is usually slower, more expensive, and more sophisticated. To obtain a reasonable task execution speed and disturbance rejection capability, active interaction

control has to be used in combination with some degree of passive compliance [9.2]: feedback, by definition, always comes after a motion and force error has occurred, hence some passive compliance is needed in order to keep the reaction forces below an acceptable threshold.

Force Measurements

For a general force-controlled task, six force components are required to provide complete contact force information: three translational force components and three torques. Often, a force/torque sensor is mounted at the robot wrist [9.3], but other possibilities exist, for example, force sensors can be placed on the fingertips of robotic hands [9.4]; also, external forces and moments can be estimated via shaft torque measurements of joint torque sensors [9.5, 6]. However, the majority of the applications of force control (including industrial applications) is concerned with wrist force/torque sensors. In this case, the weight and inertia of the tool mounted between the sensor and the environment (i. e., the robot end-effector) is assumed to be negligible or suitably compensated from the force/torque measurements. The force signals may be obtained using strain measurements, which results in a stiff sensor, or deformation measurements (e.g., optically), resulting in a compliant sensor. The latter approach has an advantage if additional passive compliance is desired.

9.1.2 From Indirect Force Control to Hybrid Force/Motion Control

Active interaction control strategies can be grouped into two categories: those performing indirect force control and those performing direct force control. The main difference between the two categories is that the former achieve force control via motion control, without explicit closure of a force feedback loop; the latter instead offer the possibility of controlling the contact force and moment to a desired value, thanks to the closure of a force feedback loop.

To the first category belongs *impedance control* (or *admittance control*) [9.7, 8], where the deviation of the end-effector motion from the desired motion due to the interaction with the environment is related to the contact force through a mechanical impedance/admittance with adjustable parameters. A robot manipulator under impedance (or admittance) control is described by an equivalent mass–spring–damper system with adjustable parameters. This relationship is an impedance if the robot control reacts to the motion deviation by generating forces, while it corresponds to an admittance if the robot control reacts to interaction forces by imposing a deviation from the desired motion. Special cases

of impedance and admittance control are *stiffness control* and *compliance control* [9.9], respectively, where only the static relationship between the end-effector position and orientation deviation from the desired motion and the contact force and moment is considered. Notice that, in the robot control literature, the terms impedance control and admittance control are often used to refer to the same control scheme; the same happens for stiffness and compliance control. Moreover, if only the relationship between the contact force and moment and the end-effector linear and angular velocity is of interest, the corresponding control scheme is referred to as *damping control* [9.10].

Indirect force control schemes do not require, in principle, measurements of contact forces and moments; the resulting impedance or admittance is typically nonlinear and coupled. However, if a force/torque sensor is available, then force measurements can be used in the control scheme to achieve a linear and decoupled behavior.

Differently from indirect force control, direct force control requires an explicit model of the interaction task. In fact, the user has to specify the desired motion and the desired contact force and moment in a consistent way with respect to the constraints imposed by the environment. A widely adopted strategy belonging to this category is *hybrid force/motion control*, which aims at controlling the motion along the unconstrained task directions and force (and moment) along the constrained task directions. The starting point is the observation that, for many robotic tasks, it is possible to introduce an orthogonal reference frame, known as the compliance frame [9.11] (or task frame [9.12]) which allows one to specify the task in terms of natural and artificial constraints acting along and about the three orthogonal axes of this frame. Based on this decomposition, hybrid force/motion control allows simultaneous control of both the contact force and the end-effector motion in two mutually independent subspaces. Simple selection matrices acting on both the desired and feedback quantities serve this purpose for planar contact surfaces [9.13], whereas suitable projection matrices must be used for general contact tasks, which can also be derived from the explicit constraint equations [9.14–16]. Several implementation of hybrid motion control schemes are available, e.g., based on inverse dynamics control in the operational space [9.17], passivity-based control [9.18], or outer force control loops closed around inner motion loops, typically available in industrial robots [9.2].

If an accurate model of the environment is not available, the force control action and the motion control action can be superimposed, resulting in a *parallel force/position control* scheme. In this approach, the

force controller is designed so as to dominate the motion controller; hence, a position error would be tol-

erated along the constrained task directions in order to ensure force regulation [9.19].

9.2 Indirect Force Control

To gain insight into the problems arising at the interaction between the end-effector of a robot manipulator and the environment, it is worth analyzing the effects of a motion control strategy in the presence of a contact force and moment. To this aim, assume that a reference frame Σ_e is attached to the end-effector, and let \mathbf{p}_e denote the position vector of the origin and \mathbf{R}_e the rotation matrix with respect to a fixed base frame. The end-effector velocity is denoted by the 6×1 twist vector $\mathbf{v}_e = (\dot{\mathbf{p}}_e^T \boldsymbol{\omega}_e^T)^T$ where $\dot{\mathbf{p}}_e$ is the translational velocity and $\boldsymbol{\omega}_e$ the angular velocity, and can be computed from the $n \times 1$ joint velocity vector $\dot{\mathbf{q}}$ using the linear mapping

$$\mathbf{v}_e = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}. \quad (9.1)$$

The matrix \mathbf{J} is the $6 \times n$ end-effector geometric Jacobian. For simplicity, the case of nonredundant nonsingular manipulators is considered; therefore, $n = 6$ and the Jacobian is a square nonsingular matrix. The force \mathbf{f}_e and moment \mathbf{m}_e applied by the end-effector to the environment are the components of the wrench $\mathbf{h}_e = (\mathbf{f}_e^T \mathbf{m}_e^T)^T$.

It is useful to consider the operational space formulation of the dynamic model of a rigid robot manipulator in contact with the environment

$$\boldsymbol{\Lambda}(\mathbf{q})\dot{\mathbf{v}}_e + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v}_e + \boldsymbol{\eta}(\mathbf{q}) = \mathbf{h}_c - \mathbf{h}_e, \quad (9.2)$$

where

$$\boldsymbol{\Lambda}(\mathbf{q}) = (\mathbf{J}\mathbf{H}(\mathbf{q})^{-1}\mathbf{J}^T)^{-1}$$

is the 6×6 operational space inertia matrix,

$$\boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{J}^{-T}\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{J}^{-1} - \boldsymbol{\Lambda}(\mathbf{q})\dot{\mathbf{J}}\mathbf{J}^{-1}$$

is the wrench including centrifugal and Coriolis effects, and $\boldsymbol{\eta}(\mathbf{q}) = \mathbf{J}^{-T}\mathbf{g}(\mathbf{q})$ is the wrench of the gravitational effects; $\mathbf{H}(\mathbf{q})$, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ and $\mathbf{g}(\mathbf{q})$ are the corresponding quantities defined in the joint space. The vector $\mathbf{h}_c = \mathbf{J}^{-T}\boldsymbol{\tau}$ is the equivalent end-effector wrench corresponding to the input joint torques $\boldsymbol{\tau}$.

9.2.1 Stiffness Control

In the classical operational space formulation, the end-effector position and orientation is described by a

6×1 vector $\mathbf{x}_e = (\mathbf{p}_e^T \boldsymbol{\varphi}_e^T)^T$, where $\boldsymbol{\varphi}_e$ is a set of Euler angles extracted from \mathbf{R}_e . Hence, a desired end-effector position and orientation can be assigned in terms of a vector \mathbf{x}_d , corresponding to the position of the origin \mathbf{p}_d and the rotation matrix \mathbf{R}_d of a desired frame Σ_d . The end-effector error can be denoted as $\Delta\mathbf{x}_{de} = \mathbf{x}_d - \mathbf{x}_e$, and the corresponding velocity error, assuming a constant \mathbf{x}_d , can be expressed as $\Delta\dot{\mathbf{x}}_{de} = -\dot{\mathbf{x}}_e = -\mathbf{A}^{-1}(\boldsymbol{\varphi}_e)\mathbf{v}_e$, with

$$\mathbf{A}(\boldsymbol{\varphi}_e) = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{T}(\boldsymbol{\varphi}_e) \end{pmatrix},$$

where \mathbf{I} is the 3×3 identity matrix, $\mathbf{0}$ is a 3×3 null matrix, and \mathbf{T} is the 3×3 matrix of the mapping $\boldsymbol{\omega}_e = \mathbf{T}(\boldsymbol{\varphi}_e)\dot{\boldsymbol{\varphi}}_e$, depending on the particular choice of the Euler angles.

Consider the motion control law

$$\mathbf{h}_c = \mathbf{A}^{-T}(\boldsymbol{\varphi}_e)\mathbf{K}_P\Delta\mathbf{x}_{de} - \mathbf{K}_D\mathbf{v}_e + \boldsymbol{\eta}(\mathbf{q}), \quad (9.3)$$

corresponding to a simple proportional-derivative (PD) + gravity compensation control in the operational space, where \mathbf{K}_P and \mathbf{K}_D are symmetric and positive-definite 6×6 matrices.

In the absence of interaction with the environment (i. e., when $\mathbf{h}_e = \mathbf{0}$), the equilibrium $\mathbf{v}_e = \mathbf{0}$, $\Delta\mathbf{x}_{de} = \mathbf{0}$ for the closed-loop system, corresponding to the desired position and orientation for the end-effector, is asymptotically stable. The stability proof is based on the positive-definite Lyapunov function

$$V = \frac{1}{2}\mathbf{v}_e^T\boldsymbol{\Lambda}(\mathbf{q})\mathbf{v}_e + \frac{1}{2}\Delta\mathbf{x}_{de}^T\mathbf{K}_P\Delta\mathbf{x}_{de},$$

whose time derivative along the trajectories of the closed-loop system is the negative semidefinite function

$$\dot{V} = -\mathbf{v}_e^T\mathbf{K}_D\mathbf{v}_e. \quad (9.4)$$

In the presence of a constant wrench \mathbf{h}_e , using a similar Lyapunov argument, a different asymptotically stable equilibrium can be found, with a nonnull $\Delta\mathbf{x}_{de}$. The new equilibrium is the solution of the equation

$$\mathbf{A}^{-T}(\boldsymbol{\varphi}_e)\mathbf{K}_P\Delta\mathbf{x}_{de} - \mathbf{h}_e = \mathbf{0},$$

which can be written in the form

$$\Delta \mathbf{x}_{de} = \mathbf{K}_P^{-1} \mathbf{A}^T(\boldsymbol{\varphi}_e) \mathbf{h}_e, \quad (9.5)$$

or, equivalently, as

$$\mathbf{h}_e = \mathbf{A}^{-T}(\boldsymbol{\varphi}_e) \mathbf{K}_P \Delta \mathbf{x}_{de}. \quad (9.6)$$

Equation (9.6) shows that in the steady state the end-effector, under a proportional control action on the position and orientation error, behaves as a six-degree-of-freedom (DOF) spring in respect of the external force and moment \mathbf{h}_e . Thus, the matrix \mathbf{K}_P plays the role of an *active stiffness*, meaning that it is possible to act on the elements of \mathbf{K}_P so as to ensure a suitable elastic behavior of the end-effector during the interaction. Analogously, (9.5) represents a compliance relationship, where the matrix \mathbf{K}_P^{-1} plays the role of an *active compliance*. This approach, consisting of assigning a desired position and orientation and a suitable static relationship between the deviation of the end-effector position and orientation from the desired motion and the force exerted on the environment, is known as *stiffness control*.

The selection of the stiffness/compliance parameters is not easy, and strongly depends on the task to be executed. A higher value of the active stiffness means a higher accuracy of the position control at the expense of higher interaction forces. Hence, if it is expected to meet some physical constraint in a particular direction, the end-effector stiffness in that direction should be made low to ensure low interaction forces. Conversely, along the directions where physical constraints are not expected, the end-effector stiffness should be made high so as to follow closely the desired position. This allows discrepancies between the desired and achievable positions due to the constraints imposed by the environment to be resolved without excessive contact forces and moments.

It must be pointed out, however, that a selective stiffness behavior along different directions cannot be effectively assigned in practice on the basis of (9.6). This can easily be understood by using the classical definition of a mechanical stiffness for two bodies connected by a 6-DOF spring, in terms of the linear mapping between the infinitesimal twist displacement of the two bodies at an unloaded equilibrium and the elastic wrench.

In the case of the active stiffness, the two bodies are, respectively, the end-effector, with the attached frame Σ_e , and a virtual body, attached to the desired frame Σ_d . Hence, from (9.6), the following mapping can be derived

$$\mathbf{h}_e = \mathbf{A}^{-T}(\boldsymbol{\varphi}_e) \mathbf{K}_P \mathbf{A}^{-1}(\boldsymbol{\varphi}_e) \delta \mathbf{x}_{de}, \quad (9.7)$$

in the case of an infinitesimal twist displacement $\delta \mathbf{x}_{de}$ defined as

$$\delta \mathbf{x}_{de} = \begin{pmatrix} \delta \mathbf{p}_{de} \\ \delta \boldsymbol{\theta}_{de} \end{pmatrix} = \begin{pmatrix} \Delta \dot{\mathbf{p}}_{de} \\ \Delta \dot{\boldsymbol{\theta}}_{de} \end{pmatrix} dt = - \begin{pmatrix} \dot{\mathbf{p}}_e \\ \dot{\boldsymbol{\theta}}_e \end{pmatrix} dt,$$

where $\Delta \dot{\mathbf{p}}_{de} = \dot{\mathbf{p}}_d - \dot{\mathbf{p}}_e$ is the time derivative of the position error $\Delta \mathbf{p}_{de} = \mathbf{p}_d - \mathbf{p}_e$ and $\Delta \dot{\boldsymbol{\theta}}_{de} = \dot{\boldsymbol{\theta}}_d - \dot{\boldsymbol{\theta}}_e$ is the angular velocity error. Equation (9.7) shows that the actual stiffness matrix is $\mathbf{A}^{-T}(\boldsymbol{\varphi}_e) \mathbf{K}_P \mathbf{A}^{-1}(\boldsymbol{\varphi}_e)$, which depends on the end-effector orientation through the vector $\boldsymbol{\varphi}_e$, so that, in practice, the selection of the stiffness parameters is quite difficult.

This problem can be overcome by defining a *geometrically consistent active stiffness*, with the same structure and properties as ideal mechanical springs.

Mechanical Springs

Consider two elastically coupled rigid bodies A and B and two reference frames Σ_a and Σ_b , attached to A and B , respectively. Assuming that at equilibrium frames Σ_a and Σ_b coincide, the compliant behavior near the equilibrium can be described by the linear mapping

$$\mathbf{h}_b^b = \mathbf{K} \delta \mathbf{x}_{ab}^b = \begin{pmatrix} \mathbf{K}_t & \mathbf{K}_c \\ \mathbf{K}_c^T & \mathbf{K}_o \end{pmatrix} \delta \mathbf{x}_{ab}^b, \quad (9.8)$$

where \mathbf{h}_b^b is the elastic wrench applied to body B , expressed in frame B , in the presence of an infinitesimal twist displacement $\delta \mathbf{x}_{ab}^b$ of frame Σ_a with respect to frame Σ_b , expressed in frame B . The elastic wrench and the infinitesimal twist displacement in (9.8) can also be expressed equivalently in frame Σ_a , since Σ_a and Σ_b coincide at equilibrium. Therefore, $\mathbf{h}_b^b = \mathbf{h}_b^a$ and $\delta \mathbf{x}_{ab}^b = \delta \mathbf{x}_{ab}^a$; moreover, for the elastic wrench applied to body A , $\mathbf{h}_a^a = \mathbf{K}_t \delta \mathbf{x}_{ba}^a = -\mathbf{h}_b^b$ being $\delta \mathbf{x}_{ba}^a = -\delta \mathbf{x}_{ab}^b$. This property of the mapping (9.8) is known as *port symmetry*.

In (9.8), \mathbf{K} is the 6×6 symmetric positive-semidefinite stiffness matrix. The 3×3 matrices \mathbf{K}_t and \mathbf{K}_o , called respectively the *translational stiffness* and *rotational stiffness*, are also symmetric. It can be shown that, if the 3×3 matrix \mathbf{K}_c , called the *coupling stiffness* is symmetric, there is maximum decoupling between rotation and translation. In this case, the point corresponding to the coinciding origins of the frames Σ_a and Σ_b is called the *center of stiffness*. Similar definitions and results can be formulated for the case of the compliance matrix $\mathbf{C} = \mathbf{K}^{-1}$. In particular, it is possible to define a *center of compliance* in the case that the off-diagonal blocks of the compliance matrix are symmetric. The center of stiffness and compliance do not necessarily coincide.

There are special cases in which no coupling exists between translation and rotation, i. e., a relative translation of the bodies results in a wrench corresponding to a pure force along an axis through the center of stiffness; also, a relative rotation of the bodies results in a wrench that is equivalent to a pure torque about an axis through the centers of stiffness. In these cases, the center of stiffness and compliance coincide. Mechanical systems with completely decoupled behavior are, e.g., the remote center of compliance (RCC) devices.

Since \mathbf{K}_t is symmetric, there exists a rotation matrix \mathbf{R}_t with respect to the frame $\Sigma_a = \Sigma_b$ at equilibrium, such that $\mathbf{K}_t = \mathbf{R}_t \mathbf{\Gamma}_t \mathbf{R}_t^T$, and $\mathbf{\Gamma}_t$ is a diagonal matrix whose diagonal elements are the *principal translational stiffnesses* in the directions corresponding to the columns of the rotation matrix \mathbf{R}_t , known as the *principal axes of translational stiffness*. Analogously, \mathbf{K}_o can be expressed as $\mathbf{K}_o = \mathbf{R}_o \mathbf{\Gamma}_o \mathbf{R}_o^T$, where the diagonal elements of $\mathbf{\Gamma}_o$ are the *principal rotational stiffnesses* about the axes corresponding to the columns of rotation matrix \mathbf{R}_o , known as the *principal axes of rotational stiffness*. Moreover, assuming that the origins of Σ_a and Σ_b at equilibrium coincide with the center of stiffness, the expression $\mathbf{K}_c = \mathbf{R}_c \mathbf{\Gamma}_c \mathbf{R}_c^T$ can be found, where the diagonal elements of $\mathbf{\Gamma}_c$ are the *principal coupling stiffnesses* along the directions corresponding to the columns of the rotation matrix \mathbf{R}_c , known as the *principal axes of coupling stiffness*. In sum, a 6×6 stiffness matrix can be specified, with respect to a frame with origin in the center of stiffness, in terms of the principal stiffness parameters and principal axes.

Notice that the mechanical stiffness defined by (9.8) describes the behavior of an ideal 6-DOF spring which stores potential energy. The potential energy function of an ideal stiffness depends only on the relative position and orientation of the two attached bodies and is port symmetric. A physical 6-DOF spring has a predominant behavior similar to the ideal one, but nevertheless it always has parasitic effects causing energy dissipation.

Geometrically Consistent Active Stiffness

To achieve a geometrically consistent 6-DOF active stiffness, a suitable definition of the proportional control action in control law (9.3) is required. This control action can be interpreted as the elastic wrench applied to the end-effector, in the presence of a *finite displacement* of the desired frame Σ_d with respect to the end-effector frame Σ_e . Hence, the properties of the ideal mechanical stiffness for small displacements should be extended to the case of finite displacements. Moreover, to guarantee asymptotic stability in the sense of Lya-

punov, a suitable potential elastic energy function must be defined.

For simplicity, it is assumed that the coupling stiffness matrix is zero. Hence, the potential elastic energy can be computed as the sum of a translational potential energy and a rotational potential energy.

The translational potential energy can be defined as

$$V_t = \frac{1}{2} \Delta \mathbf{p}_{de}^T \mathbf{K}'_{Pt} \Delta \mathbf{p}_{de}, \quad (9.9)$$

with

$$\mathbf{K}'_{Pt} = \frac{1}{2} \mathbf{R}_d \mathbf{K}_{Pt} \mathbf{R}_d^T + \frac{1}{2} \mathbf{R}_e \mathbf{K}_{Pt} \mathbf{R}_e^T,$$

where \mathbf{K}_{Pt} is a 3×3 symmetric positive-definite matrix. The use of \mathbf{K}'_{Pt} in lieu of \mathbf{K}_{Pt} in (9.9) guarantees that the potential energy is port symmetric also in the case of finite displacements. Matrices \mathbf{K}'_{Pt} and \mathbf{K}_{Pt} coincide at equilibrium (i. e., when $\mathbf{R}_d = \mathbf{R}_e$) and in the case of isotropic translational stiffness (i. e., when $\mathbf{K}_{Pt} = k_{Pt} \mathbf{I}$).

The computation of the power \dot{V}_t yields

$$\dot{V}_t = \Delta \dot{\mathbf{p}}_{de}^e f_{\Delta t}^e + \Delta \omega_{de}^e m_{\Delta t}^e,$$

where $\Delta \dot{\mathbf{p}}_{de}^e$ is the time derivative of the position displacement $\Delta \mathbf{p}_{de}^e = \mathbf{R}_e^T (\mathbf{p}_d - \mathbf{p}_e)$, while $\Delta \omega_{de}^e = \mathbf{R}_e^T (\omega_d - \omega_e)$. The vectors $f_{\Delta t}^e$ and $m_{\Delta t}^e$ are, respectively, the elastic force and moment applied to the end-effector in the presence of the finite position displacement $\Delta \mathbf{p}_{de}^e$. These vectors have the following expressions when computed in the base frame

$$f_{\Delta t} = \mathbf{K}'_{Pt} \Delta \mathbf{p}_{de} \quad m_{\Delta t} = \mathbf{K}''_{Pt} \Delta \mathbf{p}_{de}, \quad (9.10)$$

with

$$\mathbf{K}''_{Pt} = \frac{1}{2} \mathbf{S}(\Delta \mathbf{p}_{de}) \mathbf{R}_d \mathbf{K}_{Pt} \mathbf{R}_d^T,$$

where $\mathbf{S}(\cdot)$ is the skew-symmetric operator performing the vector product. The vector $\mathbf{h}_{\Delta t} = (f_{\Delta t}^T m_{\Delta t}^T)^T$ is the elastic wrench applied to the end-effector in the presence of a finite position displacement $\Delta \mathbf{p}_{de}$ and a null orientation displacement. The moment $m_{\Delta t}$ is null in the case of isotropic translational stiffness.

To define the rotational potential energy, a suitable definition of the orientation displacement between the frames Σ_d and Σ_e has to be adopted. A possible choice is the vector part of the unit quaternion $\{\eta_{de}, \epsilon_{de}^e\}$ that can be extracted from matrix $\mathbf{R}_d^e = \mathbf{R}_e^T \mathbf{R}_d$. Hence, the orientation potential energy has the form

$$V_o = 2 \epsilon_{de}^e K_{Po} \epsilon_{de}^e, \quad (9.11)$$

where \mathbf{K}_{P_0} is a 3×3 symmetric positive-definite matrix. The function V_0 is port symmetric because $\epsilon_{de}^e = -\epsilon_{ed}^d$.

The computation of the power \dot{V}_0 yields

$$\dot{V}_0 = \Delta \omega_{de}^{eT} \mathbf{m}_{\Delta_0}^e,$$

where

$$\mathbf{m}_{\Delta_0} = \mathbf{K}_{P_0}' \epsilon_{de}, \quad (9.12)$$

with

$$\mathbf{K}_{P_0}' = 2\mathbf{E}^T(\eta_{de}, \epsilon_{de}) \mathbf{R}_e \mathbf{K}_{P_0} \mathbf{R}_e^T,$$

and $\mathbf{E}(\eta_{de}, \epsilon_{de}) = \eta_{de} \mathbf{I} - \mathbf{S}(\epsilon_{de})$. The above equations show that a finite orientation displacement $\epsilon_{de} = \mathbf{R}_e^T \epsilon_{de}^e$ produces an elastic wrench $\mathbf{h}_{\Delta_0} = (\mathbf{0}^T \mathbf{m}_{\Delta_0}^T)^T$ which is equivalent to a pure moment.

Hence, the total elastic wrench in the presence of a finite position and orientation displacement of the desired frame Σ_d with respect to the end-effector frame Σ_e can be defined in the base frame as

$$\mathbf{h}_{\Delta} = \mathbf{h}_{\Delta_t} + \mathbf{h}_{\Delta_0}. \quad (9.13)$$

where \mathbf{h}_{Δ_t} and \mathbf{h}_{Δ_0} are computed according to (9.10) and (9.12), respectively.

Using (9.13) for the computation of the elastic wrench in the case of an infinitesimal twist displacement $\delta \mathbf{x}_{de}^e$ near the equilibrium, and discarding the high-order infinitesimal terms, yields the linear mapping

$$\mathbf{h}_e^e = \mathbf{K}_P \delta \mathbf{x}_{de}^e = \begin{pmatrix} \mathbf{K}_{Pt} & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{P_0} \end{pmatrix} \delta \mathbf{x}_{de}^e. \quad (9.14)$$

Therefore, \mathbf{K}_P represents the stiffness matrix of an ideal spring with respect to a frame Σ_e (coinciding with Σ_d at equilibrium) with the origin at the center of stiffness. Moreover, it can be shown, using definition (9.13), that the physical/geometrical meaning of the principal stiffnesses and of the principal axes for the matrices \mathbf{K}_{Pt} and \mathbf{K}_{P_0} are preserved also in the case of large displacements.

The above results imply that the active stiffness matrix \mathbf{K}_P can be set in a geometrically consistent way with respect to the task at hand.

Notice that geometrical consistency can also be ensured with different definitions of the orientation error in the potential orientation energy (9.11), for example, any error based on the angle/axis representation of \mathbf{R}_e^d can be adopted (the unit quaternion belongs to this category), or, more generally, homogeneous matrices or exponential coordinates (for the case of both position and orientation errors). Also, the XYZ Euler angles extracted from the matrix \mathbf{R}_e^d could be used; however, in

this case, it can be shown that the principal axes of rotational stiffness cannot be set arbitrarily but must coincide with those of the end-effector frame.

Stiffness control with a geometrically consistent active stiffness can be defined using the control law

$$\mathbf{h}_e = \mathbf{h}_{\Delta} - \mathbf{K}_D \mathbf{v}_e + \eta(\mathbf{q}), \quad (9.15)$$

with \mathbf{h}_{Δ} in (9.13). The asymptotic stability about the equilibrium in the case $\mathbf{h}_e = \mathbf{0}$ can be proven using the Lyapunov function

$$V = \frac{1}{2} \mathbf{v}_e^T \mathbf{\Lambda}(\mathbf{q}) \mathbf{v}_e + V_t + V_0,$$

with V_t and V_0 given in (9.9) and (9.11), respectively, whose time derivative along the trajectories of the closed-loop system, in case the frame Σ_d is motionless, has the same expression as in (9.4). When $\mathbf{h}_e \neq \mathbf{0}$, a different asymptotically stable equilibrium can be found, corresponding to a nonnull displacement of the desired frame Σ_d with respect to the end-effector frame Σ_e . The new equilibrium is the solution of the equation $\mathbf{h}_{\Delta} = \mathbf{h}_e$.

Stiffness control allows to keep the interaction force and moment limited at the expense of the end-effector position and orientation error, with a proper choice of the stiffness matrix, without the need of a force/torque sensor. However, in the presence of disturbances (e.g., joint friction) which can be modeled as an equivalent end-effector wrench, the adoption of low values for the active stiffness may produce large deviations with respect to the desired end-effector position and orientation, also in the absence of interaction with the environment.

9.2.2 Impedance Control

Stiffness control is designed to achieve a desired *static* behavior of the interaction. In fact, the dynamics of the controlled system depends on that of the robot manipulator, which is nonlinear and coupled. A more demanding objective may be that of achieving a desired *dynamic* behavior for the end-effector, e.g., that of a second-order mechanical system with six degrees of freedom, characterized by a given mass, damping, and stiffness, known as mechanical *impedance*.

The starting point to pursue this goal may be the acceleration-resolved approach used for motion control, which is aimed at decoupling and linearizing the nonlinear robot dynamics at the acceleration level via an inverse dynamics control law. In the presence of interaction with the environment, the control law

$$\mathbf{h}_e = \mathbf{\Lambda}(\mathbf{q}) \boldsymbol{\alpha} + \mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} + \eta(\mathbf{q}) + \mathbf{h}_e \quad (9.16)$$

cast into the dynamic model (9.2) results in

$$\dot{\mathbf{v}}_e = \boldsymbol{\alpha}, \quad (9.17)$$

where $\boldsymbol{\alpha}$ is a properly designed control input with the meaning of an acceleration referred to the base frame.

Considering the identity $\dot{\mathbf{v}}_e = \bar{\mathbf{R}}_e^T \dot{\mathbf{v}}_e^e + \dot{\bar{\mathbf{R}}}_e^T \mathbf{v}_e^e$, with

$$\bar{\mathbf{R}}_e = \begin{pmatrix} \mathbf{R}_e & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_e \end{pmatrix},$$

the choice

$$\boldsymbol{\alpha} = \bar{\mathbf{R}}_e^T \boldsymbol{\alpha}^e + \dot{\bar{\mathbf{R}}}_e^T \mathbf{v}_e^e \quad (9.18)$$

gives

$$\dot{\mathbf{v}}_e^e = \boldsymbol{\alpha}^e, \quad (9.19)$$

where the control input $\boldsymbol{\alpha}^e$ has the meaning of an acceleration referred to the end-effector frame Σ_e . Hence, setting

$$\boldsymbol{\alpha}^e = \dot{\mathbf{v}}_d^e + \mathbf{K}_M^{-1} (\mathbf{K}_D \Delta \mathbf{v}_{de}^e + \mathbf{h}_\Delta^e - \mathbf{h}_e^e), \quad (9.20)$$

the following expression can be found for the closed-loop system

$$\mathbf{K}_M \Delta \dot{\mathbf{v}}_{de}^e + \mathbf{K}_D \Delta \mathbf{v}_{de}^e + \mathbf{h}_\Delta^e = \mathbf{h}_e^e, \quad (9.21)$$

where \mathbf{K}_M and \mathbf{K}_D are 6×6 symmetric and positive-definite matrices, $\Delta \dot{\mathbf{v}}_{de}^e = \dot{\mathbf{v}}_d^e - \dot{\mathbf{v}}_e^e$, $\Delta \mathbf{v}_{de}^e = \mathbf{v}_d^e - \mathbf{v}_e^e$, $\dot{\mathbf{v}}_d^e$ and \mathbf{v}_d^e are, respectively, the acceleration and the velocity of a desired frame Σ_d and \mathbf{h}_Δ^e is the elastic wrench (9.13); all the quantities are referred to the end-effector frame Σ_e .

The above equation describing the dynamic behavior of the controlled end-effector can be interpreted as a generalized mechanical impedance. The asymptotic

stability of the equilibrium in the case $\mathbf{h}_e = \mathbf{0}$ can be proven by considering the Lyapunov function

$$V = \frac{1}{2} \Delta \mathbf{v}_{de}^{eT} \mathbf{K}_M \Delta \mathbf{v}_{de}^e + V_t + V_o, \quad (9.22)$$

where V_t and V_o are defined in (9.9) and (9.11), respectively, and whose time derivative along the trajectories of system (9.21) is the negative semidefinite function

$$\dot{V} = -\Delta \mathbf{v}_{de}^{eT} \mathbf{K}_D \Delta \mathbf{v}_{de}^e.$$

When $\mathbf{h}_e \neq \mathbf{0}$, a different asymptotically stable equilibrium can be found, corresponding to a nonnull displacement of the desired frame Σ_d with respect to the end-effector frame Σ_e . The new equilibrium is the solution of the equation $\mathbf{h}_\Delta = \mathbf{h}_e$.

In case Σ_d is constant, (9.21) has the meaning of a true 6-DOF mechanical impedance if \mathbf{K}_M is chosen as

$$\mathbf{K}_M = \begin{pmatrix} m\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{M} \end{pmatrix},$$

where m is a mass and \mathbf{M} is a 3×3 inertia tensor, and \mathbf{K}_D is chosen as a block-diagonal matrix with 3×3 blocks. The physically equivalent system is a body of mass m with inertia tensor \mathbf{M} with respect to a frame Σ_e attached to the body, subject to an external wrench \mathbf{h}_e^e . This body is connected to a virtual body attached to frame Σ_d through a 6-DOF ideal spring with stiffness matrix \mathbf{K}_P and is subject to viscous forces and moments with damping \mathbf{K}_D . The function V in (9.22) represents the total energy of the body: the sum of the kinetic and potential elastic energy.

A block diagram of the resulting impedance control is sketched in Fig. 9.1. The impedance control computes the acceleration input as in (9.18) and (9.20) on the basis of the position and orientation feedback as well as the force and moment measurements. Then, the inverse dynamics control law computes the torques for the joint actuators $\boldsymbol{\tau} = \mathbf{J}^T \mathbf{h}_e$ with \mathbf{h}_e in (9.16). This control scheme, in the absence of interaction, guarantees that the end-effector frame Σ_e asymptotically follows the desired frame Σ_d . In the presence of contact with the environment, a compliant dynamic behavior is imposed on the end-effector, according to the impedance (9.21), and the contact wrench is bounded at the expense of a finite position and orientation displacement between Σ_d and Σ_e . Differently from stiffness control, a force/torque sensor is required for the measurement of the contact force and moment.

In the case that the force/torque sensor is not available, the measure of the external wrench \mathbf{h}_e cannot be used in the controller and thus the configuration-

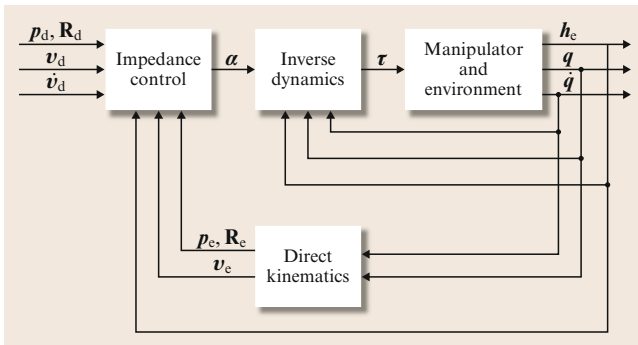

Fig. 9.1 Impedance control

independent impedance behaviour (9.21) cannot be obtained anymore. However, a desired impedance behaviour can be still achieved with the control law

$$\mathbf{h}_c = \mathbf{\Lambda}(\mathbf{q})\dot{\mathbf{v}}_d + \mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v}_d + \mathbf{K}_D\Delta\mathbf{v}_{de} + \mathbf{h}_\Delta + \boldsymbol{\eta}(\mathbf{q}) \quad (9.23)$$

in place of (9.16), where \mathbf{K}_D is a 6×6 positive-definite matrix and \mathbf{h}_Δ is the elastic wrench (9.13). The resulting closed-loop equation is

$$\mathbf{\Lambda}(\mathbf{q})\Delta\dot{\mathbf{v}}_{de} + (\mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}_D)\Delta\mathbf{v}_{de} + \mathbf{h}_\Delta = \mathbf{h}_c,$$

representing an impedance behaviour which preserves the actual operational space inertia matrix $\mathbf{\Lambda}(\mathbf{q})$ of the robot. In the above equation, the centrifugal and Coriolis wrench $\mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\Delta\mathbf{v}_{de}$ is required to preserve the mechanical properties of a configuration-dependent inertia and to prove the stability similarly to (9.21). In case Σ_d is constant, control law (9.23) reduces to the stiffness control law (9.15).

Pioneering experiments on stiffness control and impedance control and without without force sensing are presented in [VIDEO 684](#). [VIDEO 686](#) reports experiments on impedance control based on a geometrically consistent active stiffness.

Implementation Issues

The selection of good impedance parameters ensuring a satisfactory behavior is not an easy task. In fact, the dynamics of the closed-loop system is different in free space and during interaction. The control objectives are different as well, since motion tracking and disturbance rejection must be ensured in free space, while, during the interaction, the main goal is achieving a suitable compliant dynamic behavior for the end-effector. Notice also that the dynamics of the controlled system during the interaction depends on the dynamics of the environment.

To gain insight into these problems, assume that the interaction of the end-effector with the environment can be approximated by that derived from an ideal 6-DOF spring connecting end-effector frame Σ_e to the environment frame Σ_o . Therefore, according to (9.8), the elastic wrench exerted by the end-effector on the environment, in the presence of an infinitesimal twist displacement of Σ_e with respect to Σ_o , can be computed as

$$\mathbf{h}_e^c = \mathbf{K}\delta\mathbf{x}_{e_o}^c, \quad (9.24)$$

where Σ_e and Σ_o coincide at equilibrium and \mathbf{K} is a stiffness matrix. The above model holds only in the

presence of interaction, while the contact wrench is null when the end-effector moves in free space.

The disturbances acting on the robot manipulator and the unmodeled dynamics (joint friction, modeling errors, etc.) may be taken into account by introducing an additive term on the right-hand side of the dynamic model of the robot manipulator (9.2), corresponding to an equivalent disturbance wrench acting on the end-effector. This term produces an additive acceleration disturbance $\boldsymbol{\gamma}^c$ on the right-hand side of (9.19). Therefore, using the control law (9.20), the following closed-loop impedance equation can be found

$$\mathbf{K}_M\Delta\dot{\mathbf{v}}_{de}^c + \mathbf{K}_D\Delta\mathbf{v}_{de}^c + \mathbf{h}_\Delta^c = \mathbf{h}_e^c + \mathbf{K}_M\boldsymbol{\gamma}^c. \quad (9.25)$$

The tuning procedure for the impedance parameters can be set up starting from the linearized model that can be computed from (9.25) in the case of infinitesimal displacements, i. e.,

$$\begin{aligned} \mathbf{K}_M\delta\ddot{\mathbf{x}}_{de}^c + \mathbf{K}_D\delta\dot{\mathbf{x}}_{de}^c + (\mathbf{K}_P + \mathbf{K})\delta\mathbf{x}_{de}^c \\ = \mathbf{K}\delta\mathbf{x}_{do}^c + \mathbf{K}_M\boldsymbol{\gamma}^c, \end{aligned} \quad (9.26)$$

where (9.24) and the equality $\delta\mathbf{x}_{e_o}^c = -\delta\mathbf{x}_{de}^c + \delta\mathbf{x}_{do}^c$ have been used. The above equation is valid both for constrained ($\mathbf{K} \neq \mathbf{0}$) and for free motion ($\mathbf{K} = \mathbf{0}$).

It is evident that suitable dynamics of the position and orientation errors can be set by suitably choosing the matrix gains \mathbf{K}_M , \mathbf{K}_D , and \mathbf{K}_P . This task is easier under the hypothesis that all the matrices are diagonal, resulting in a decoupled behavior for the six components of the infinitesimal twist displacement. In this case, the transient behavior of each component can be set, e.g., by assigning the natural frequency and damping ratio with the relations

$$\omega_n = \sqrt{\frac{k_P + k}{k_M}}, \quad \zeta = \frac{1}{2} \frac{k_D}{\sqrt{k_M(k_P + k)}}.$$

Hence, if the gains are chosen so that a given natural frequency and damping ratio are ensured during the interaction (i. e., for $k \neq 0$), a smaller natural frequency with a higher damping ratio will be obtained when the end-effector moves in free space (i. e., for $k = 0$). As for the steady-state performance, the end-effector error for the generic component is

$$\delta x_{de} = \frac{k}{(k_P + k)}\delta x_{do} + \frac{k_M}{k_P + k}\boldsymbol{\gamma}$$

and the corresponding interaction force is

$$\mathbf{h} = \frac{k_P k}{k_P + k}\delta\mathbf{x}_{do} - \frac{k_M k}{k_P + k}\boldsymbol{\gamma}.$$

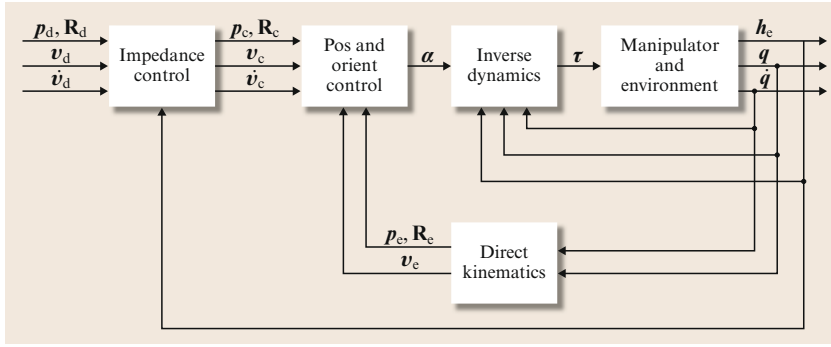

Fig. 9.2 Impedance control with inner motion control loop (admittance control)

The above relations show that, during interaction, the contact force can be made small at the expense of a large position error in steady state, as long as the active stiffness k_p is set low with respect to the stiffness of the environment k , and vice versa. However, both the contact force and the position error also depend on the external disturbance γ ; in particular, the lower k_p , the higher the influence of γ on both δx_{de} and h . Moreover, a low active stiffness k_p may result in a large position error also in the absence of interaction (i. e., when $k = 0$).

Admittance Control

A solution to this drawback can be devised by separating motion control from impedance control as follows. The motion control action is purposefully made stiff so as to enhance disturbance rejection but, rather than ensuring tracking of the desired end-effector position and orientation, it ensures tracking of a reference position and orientation resulting from the impedance control action. In other words, the desired position and orientation, together with the measured contact wrench, are input to the impedance equation which, via a suitable integration, generates the position and orientation to be used as a reference for the motion control.

To implement this solution, it is worth introducing a reference frame other than the desired frame Σ_d . This frame is referred to as the *compliant frame* Σ_c , and is specified by the quantities p_c, R_c, v_c , and \dot{v}_c that are computed from p_d, R_d, v_d , and \dot{v}_d and the measured wrench h_c , by integrating the equation

$$\mathbf{K}_M \Delta \dot{v}_c + \mathbf{K}_D \Delta v_c + h_\Delta^c = h^c, \quad (9.27)$$

where h_Δ^c is the elastic wrench in the presence of a finite displacement between the desired frame Σ_d and the compliant frame Σ_c . Then, a motion control strategy, based on inverse dynamics, is designed so that the end-effector frame Σ_e is taken to coincide with the compliant frame Σ_c . To guarantee the stability of the overall system, the bandwidth of the motion controller should be higher than the bandwidth of the impedance controller.

A block diagram of the resulting scheme is sketched in Fig. 9.2. It is evident that, in the absence of interaction, the compliant frame Σ_c coincides with the desired frame Σ_d and the dynamics of the position and orientation error, as well as the disturbance rejection capabilities, depend only on the gains of the inner motion control loop. On the other hand, the dynamic behavior in the presence of interaction is imposed by the impedance gains (9.27).

The control scheme of Fig. 9.2 is also known as *admittance control* because, in (9.27), the measured force (the input) is used to compute the motion of the compliant frame (the output), given the motion of the desired frame; a mapping with a force as input and a position or velocity as output corresponds to a mechanical *admittance*. Vice versa, (9.21), mapping the end-effector displacement (the input) from the desired motion trajectory into the contact wrench (the output), has the meaning of a mechanical *impedance*. Experiments on admittance control are reported in [VIDEO 685](#).

Simplified Schemes

The inverse dynamics control is model based and requires modification of current industrial robot controllers, which are usually equipped with independent proportional–integral (PI) joint velocity controllers with very high bandwidth. These controllers are able to decouple the robot dynamics to a large extent, especially in the case of slow motion, and to mitigate the effects of external forces on the manipulator motion if the environment is sufficiently compliant. Hence, the closed-loop dynamics of the controlled robot can be approximated by

$$\dot{q} = \dot{q}_r$$

in joint space, or equivalently

$$\dot{v}_e = v_r \quad (9.28)$$

in the operational space, where \dot{q}_r and v_r are the control signals for the inner velocity motion loop generated by

a suitably designed outer control loop. These control signals are related by

$$\dot{q}_r = \mathbf{J}^{-1}(\mathbf{q})\mathbf{v}_r.$$

The velocity \mathbf{v}_r , corresponding to a *velocity-resolved control*, can be computed as

$$\mathbf{v}_r^c = \mathbf{v}_d^c + \mathbf{K}_D^{-1}(\mathbf{h}_\Delta^c - \mathbf{h}_e^c),$$

where the control input has been referred to the end-effector frame, \mathbf{K}_D is a 6×6 positive-definite matrix and \mathbf{h}_Δ is the elastic wrench (9.13) with stiffness matrix \mathbf{K}_p . The resulting closed-loop equation is

$$\mathbf{K}_D \Delta \mathbf{v}_{dc}^c + \mathbf{h}_\Delta^c = \mathbf{h}_e^c,$$

9.3 Interaction Tasks

Indirect force control does not require explicit knowledge of the environment, although to achieve a satisfactory dynamic behavior the control parameters have to be tuned for a particular task. On the other hand, a model of the interaction task is required for the synthesis of direct force control algorithms.

An interaction task is characterized by complex contact situations between the manipulator and the environment. To guarantee proper task execution, it is necessary to have an analytical description of the interaction force and moment, which is very demanding from a modeling viewpoint.

A real contact situation is a naturally distributed phenomenon in which the local characteristics of the contact surfaces as well as the global dynamics of the manipulator and environment are involved. In detail:

- The environment imposes kinematic constraints on the end-effector motion, due to one or more contacts of different type, and a reaction wrench arises when the end-effector tends to violate the constraints (e.g., the case of a robot sliding a rigid tool on a frictionless rigid surface).
- The end-effector, while being subject to kinematic constraints, may also exert a dynamic wrench on the environment, in the presence of environment dynamics (e.g., the case of a robot turning a crank, when the crank dynamics is relevant, or a robot pushing against a compliant surface).
- The contact wrench may depend on the structural compliance of the robot, due to the finite stiffness of the joints and links of the manipulator, as well as

corresponding to a compliant behavior of the end-effector characterized by a damping \mathbf{K}_D and a stiffness \mathbf{K}_p . In the case $\mathbf{K}_p = \mathbf{0}$, the resulting scheme is known as *damping control*.

Alternatively, an admittance-type control scheme can be adopted, where the motion of a compliant frame Σ_c can be computed as the solution of the differential equation

$$\mathbf{K}_D \Delta \mathbf{v}_{dc}^c + \mathbf{h}_\Delta^c = \mathbf{h}_e^c$$

in terms of the position \mathbf{p}_c , orientation \mathbf{R}_c , and velocity twist \mathbf{v}_c , where the inputs are the motion variables of the desired frame Σ_d and the contact wrench \mathbf{h}_e^c . The motion variables of Σ_c are then input to an inner position and velocity controller. In the case $\mathbf{K}_D = \mathbf{0}$, the resulting scheme is known as *compliance control*.

of the wrist force/torque sensor or of the tool (e.g., an end-effector mounted on an **RCC** device).

- Local deformation of the contact surfaces may occur during the interaction, producing distributed contact areas (e.g., the case of a soft contact surface of the tool or of the environment).
- Static and dynamic friction may occur in the case of non ideally smooth contact surfaces.

The design of the interaction control and the performance analysis are usually carried out under simplifying assumptions. The following two cases are considered:

1. The robot and the environment are perfectly rigid and purely kinematics constraints are imposed by the environment,
2. The robot is perfectly rigid, all the compliance in the system is localized in the environment, and the contact wrench is approximated by a linear elastic model.

In both cases, frictionless contact is assumed. It is obvious that these situations are only ideal. However, the robustness of the control should be able to cope with situations where some of the ideal assumptions are relaxed. In that case the control laws may be adapted to deal with nonideal characteristics.

9.3.1 Rigid Environment

The kinematic constraints imposed by the environment can be represented by a set of equations that the

variables describing the end-effector position and orientation must satisfy; since these variables depend on the joint variables through the direct kinematic equations, the constraint equations can also be expressed in the joint space as

$$\boldsymbol{\phi}(\mathbf{q}) = \mathbf{0}. \quad (9.29)$$

The vector $\boldsymbol{\phi}$ is an $m \times 1$ function, with $m < n$, where n is the number of joints of the manipulator, assumed to be nonredundant; without loss of generality, the case $n = 6$ is considered. Constraints of the form (9.29), involving only the generalized coordinates of the system, are known as holonomic constraints. The case of time-varying constraints of the form $\boldsymbol{\phi}(\mathbf{q}, t) = \mathbf{0}$ is not considered here but can be analyzed in a similar way. Moreover, only bilateral constraints expressed by equalities of the form (9.29) are of concern; this means that the end-effector always keeps contact with the environment. The analysis presented here is known as *kinetostatic analysis*.

It is assumed that the vector (9.29) is twice differentiable and that its m components are linearly independent at least locally in a neighborhood of the operating point. Hence, differentiation of (9.29) yields

$$\mathbf{J}_\phi(\mathbf{q})\dot{\mathbf{q}} = \mathbf{0}, \quad (9.30)$$

where $\mathbf{J}_\phi(\mathbf{q}) = \partial\boldsymbol{\phi}/\partial\mathbf{q}$ is the $m \times 6$ Jacobian of $\boldsymbol{\phi}(\mathbf{q})$, known as the *constraint Jacobian*. By virtue of the above assumption, $\mathbf{J}_\phi(\mathbf{q})$ is of rank m at least locally in a neighborhood of the operating point.

In the absence of friction, the generalized interaction forces are represented by a reaction wrench that tends to violate the constraints. This end-effector wrench produces reaction torques at the joints that can be computed using the principle of virtual work as

$$\boldsymbol{\tau}_e = \mathbf{J}_\phi^T(\mathbf{q})\boldsymbol{\lambda},$$

where $\boldsymbol{\lambda}$ is an $m \times 1$ vector of Lagrange multipliers. The end-effector wrench corresponding to $\boldsymbol{\tau}_e$ can be computed as

$$\mathbf{h}_e = \mathbf{J}^{-T}(\mathbf{q})\boldsymbol{\tau}_e = \mathbf{S}_f(\mathbf{q})\boldsymbol{\lambda}, \quad (9.31)$$

where

$$\mathbf{S}_f = \mathbf{J}^{-T}(\mathbf{q})\mathbf{J}_\phi^T(\mathbf{q}). \quad (9.32)$$

From (9.31) it follows that \mathbf{h}_e belongs to the m -dimensional vector space spanned by the columns of the $6 \times m$ matrix \mathbf{S}_f . The inverse of the linear transformation (9.31) is computed as

$$\boldsymbol{\lambda} = \mathbf{S}_f^\dagger(\mathbf{q})\mathbf{h}_e, \quad (9.33)$$

where \mathbf{S}_f^\dagger denotes a weighted pseudoinverse of the matrix \mathbf{S}_f , i.e.,

$$\mathbf{S}_f^\dagger = (\mathbf{S}_f^T \mathbf{W} \mathbf{S}_f)^{-1} \mathbf{S}_f^T \mathbf{W}, \quad (9.34)$$

where \mathbf{W} is a suitable weighting matrix.

Notice that, while the range space of the matrix \mathbf{S}_f in (9.32) is uniquely defined by the geometry of the contact, the matrix \mathbf{S}_f itself is not unique; also, the constraint equations (9.29), the corresponding Jacobian \mathbf{J}_ϕ as well as the pseudoinverse \mathbf{S}_f^\dagger and the vector $\boldsymbol{\lambda}$ are not uniquely defined.

In general, the physical units of measure of the elements of $\boldsymbol{\lambda}$ are not homogeneous and the columns of the matrix \mathbf{S}_f , as well as of the matrix \mathbf{S}_f^\dagger , do not necessarily represent homogeneous entities. This may produce invariance problems in the transformation (9.33) if \mathbf{h}_e represents a measured wrench that is subject to disturbances and, as a result, may have components outside the range space of \mathbf{S}_f . If a physical unit or a reference frame is changed, the matrix \mathbf{S}_f undergoes a transformation; however, the result of (9.33) with the transformed pseudoinverse in general depends on the adopted physical units or on the reference frame. The reason is that the pseudoinverse is the weighted least-squares solution of a minimization problem based on the norm of the vector $\mathbf{h}_e - \mathbf{S}_f(\mathbf{q})\boldsymbol{\lambda}$, and the invariance can be guaranteed only if a physically consistent norm of this vector is used. In the ideal case that \mathbf{h}_e is in the range space of \mathbf{S}_f , there is a unique solution for $\boldsymbol{\lambda}$ in (9.33), regardless of the weighting matrix, and hence the invariance problem does not appear.

A possible solution consists of choosing \mathbf{S}_f so that its columns represent linearly independent wrenches. This implies that (9.31) gives \mathbf{h}_e as a linear combination of wrenches and $\boldsymbol{\lambda}$ is a dimensionless vector. A physically consistent norm on the wrench space can be defined based on the quadratic form $\mathbf{h}_e^T \mathbf{K}^{-1} \mathbf{h}_e$, which has the meaning of an elastic energy if \mathbf{K} is a positive-definite matrix corresponding to a stiffness. Hence, the choice $\mathbf{W} = \mathbf{K}^{-1}$ can be made for the weighting matrix of the pseudoinverse.

Notice that, for a given \mathbf{S}_f , the constraint Jacobian can be computed from (9.32) as $\mathbf{J}_\phi(\mathbf{q}) = \mathbf{S}_f^T \mathbf{J}(\mathbf{q})$; moreover, the constraint equations can be derived by integrating (9.30).

Using (9.1) and (9.32), the equality (9.30) can be rewritten in the form

$$\mathbf{J}_\phi(\mathbf{q})\mathbf{J}^{-1}(\mathbf{q})\mathbf{J}(\mathbf{q})\dot{\mathbf{q}} = \mathbf{S}_f^T \mathbf{v}_e = \mathbf{0}, \quad (9.35)$$

which, by virtue of (9.31), is equivalent to

$$\mathbf{h}_e^T \mathbf{v}_e = 0. \quad (9.36)$$

Equation (9.36) represents the kinetostatic relationship, known as *reciprocity*, between the ideal reaction wrench \mathbf{h}_e (belonging to the so-called *force-controlled* subspace) and the end-effector twist that obeys the constraints (belonging to the so-called *velocity-controlled* subspace). The concept of reciprocity, expressing the physical fact that, in the hypothesis of rigid and frictionless contact, the wrench does not cause any work against the twist, is often confused with the concept of *orthogonality*, which makes no sense in this case because twists and wrenches belong to different spaces.

Equations ((9.35)) and (9.36) imply that the velocity-controlled subspace is the reciprocal complement of the m -dimensional force-controlled subspace, identified by the range of matrix \mathbf{S}_f . Hence, the dimension of the velocity-controlled subspace is $6 - m$ and a $6 \times (6 - m)$ matrix \mathbf{S}_v can be defined, whose columns span the velocity-controlled subspace, i. e.,

$$\mathbf{v}_e = \mathbf{S}_v(\mathbf{q})\mathbf{v}, \quad (9.37)$$

where \mathbf{v} is a suitable $(6 - m) \times 1$ vector. From (9.35) and (9.37) the following equality holds

$$\mathbf{S}_f^T(\mathbf{q})\mathbf{S}_v(\mathbf{q}) = \mathbf{0}; \quad (9.38)$$

moreover, the inverse of the linear transformation (9.37) can be computed as

$$\mathbf{v} = \mathbf{S}_v^\dagger(\mathbf{q})\mathbf{v}_e, \quad (9.39)$$

where \mathbf{S}_v^\dagger denotes a suitable weighted pseudoinverse of the matrix \mathbf{S}_v , computed as in (9.34).

Notice that, as for the case of \mathbf{S}_f , although the range space of the matrix \mathbf{S}_v is uniquely defined, the choice of the matrix \mathbf{S}_v itself is not unique. Moreover, the columns of \mathbf{S}_v are not necessarily twists and the scalar \mathbf{v} may have nonhomogeneous physical dimensions. However, in order to avoid invariance problems analogous to that considered for the case of \mathbf{S}_f , it is convenient to select the columns of \mathbf{S}_v as twists so that the vector \mathbf{v} is dimensionless; moreover, the weighting matrix used to compute the pseudoinverse in (9.39) can be set as $\mathbf{W} = \mathbf{M}$, being \mathbf{M} a 6×6 inertia matrix; this corresponds to defining a norm in the space of twists based on the kinetic energy. It is worth observing that the transformation matrices of twists and wrenches, corresponding to a change of reference frame, are different; however, if twists are defined with angular velocity on top and translational velocity on bottom, then their transformation matrix is the same as for wrenches.

The matrix \mathbf{S}_v may also have an interpretation in terms of Jacobians, as for \mathbf{S}_f in (9.32). Due to the presence of m independent holonomic constraints (9.29),

the configuration of the robot in contact with the environment can be described in terms of a $(6 - m) \times 1$ vector \mathbf{r} of independent variables. From the implicit function theorem, this vector can be defined as

$$\mathbf{r} = \boldsymbol{\psi}(\mathbf{q}), \quad (9.40)$$

where $\boldsymbol{\psi}(\mathbf{q})$ is any $(6 - m) \times 1$ twice-differentiable vector function such that the m components of $\boldsymbol{\phi}(\mathbf{q})$ and the $n - m$ components of $\boldsymbol{\psi}(\mathbf{q})$ are linearly independent at least locally in a neighborhood of the operating point. This means that the mapping (9.40), together with the constraint (9.29), is locally invertible, with inverse defined as

$$\mathbf{q} = \boldsymbol{\rho}(\mathbf{r}), \quad (9.41)$$

where $\boldsymbol{\rho}(\mathbf{r})$ is a 6×1 twice-differentiable vector function. Equation (9.41) explicitly provides all the joint vectors which satisfy the constraint (9.29). Moreover, the joint velocity vectors that satisfy (9.30) can be computed as

$$\dot{\mathbf{q}} = \mathbf{J}_\rho(\mathbf{r})\dot{\mathbf{r}},$$

where $\mathbf{J}_\rho(\mathbf{r}) = \partial \boldsymbol{\rho} / \partial \mathbf{r}$ is a $6 \times (6 - m)$ full-rank Jacobian matrix. Therefore, the following equality holds

$$\mathbf{J}_\phi(\mathbf{q})\mathbf{J}_\rho(\mathbf{r}) = \mathbf{0},$$

which can be interpreted as a reciprocity condition between the subspace of the reaction torques spanned by the columns of the matrix \mathbf{J}_ϕ^T and the subspace of the constrained joint velocities spanned by the columns of the matrix \mathbf{J}_ρ .

Rewriting the above equation as

$$\mathbf{J}_\phi(\mathbf{q})\mathbf{J}(\mathbf{q})^{-1}\mathbf{J}(\mathbf{q})\mathbf{J}_\rho(\mathbf{r}) = \mathbf{0},$$

and taking into account (9.32) and (9.38), the matrix \mathbf{S}_v can be expressed as

$$\mathbf{S}_v = \mathbf{J}(\mathbf{q})\mathbf{J}_\rho(\mathbf{r}), \quad (9.42)$$

which, by virtue of (9.40) and (9.41), it can be equivalently expressed as a function of either \mathbf{q} or \mathbf{r} .

The matrices \mathbf{S}_f and \mathbf{S}_v , and their pseudoinverse \mathbf{S}_f^\dagger and \mathbf{S}_v^\dagger are known as selection matrices. They play a fundamental role for the task specification, i. e., the specification of the desired end-effector motion and interaction forces and moments, as well as for the control synthesis.

9.3.2 Compliant Environment

In many applications, the interaction wrench between the end-effector and a compliant environment can be approximated by an ideal elastic model of the form (9.24). However, since the stiffness matrix \mathbf{K} is positive definite, this model describes a fully constrained case, when the environment deformation coincides with the infinitesimal twist displacement of the end-effector. In general, however, the end-effector motion is only partially constrained by the environment and this situation can be modeled by introducing a suitable positive-semidefinite stiffness matrix.

The stiffness matrix describing the partially constrained interaction between the end-effector and the environment can be computed by modeling the environment as a couple of rigid bodies, S and O , connected through an ideal 6-DOF spring of compliance $\mathbf{C} = \mathbf{K}^{-1}$. Body S is attached to a frame Σ_s and is in contact with the end-effector; body O is attached to a frame Σ_o which, at equilibrium, coincides with frame Σ_s . The environment deformation about the equilibrium, in the presence of a wrench \mathbf{h}_s , is represented by the infinitesimal twist displacement $\delta\mathbf{x}_{so}$ between frames Σ_s and Σ_o , which can be computed as

$$\delta\mathbf{x}_{so} = \mathbf{C}\mathbf{h}_s. \quad (9.43)$$

All the quantities hereafter are referred to frame Σ_s but the superscript s is omitted for brevity.

For the considered contact situation, the end-effector twist does not completely belong to the ideal velocity subspace, corresponding to a rigid environment, because the environment can deform. Therefore, the infinitesimal twist displacement of the end-effector frame Σ_e with respect to Σ_o can be decomposed as

$$\delta\mathbf{x}_{eo} = \delta\mathbf{x}_v + \delta\mathbf{x}_f, \quad (9.44)$$

where $\delta\mathbf{x}_v$ is the end-effector infinitesimal twist displacement in the velocity-controlled subspace, defined as the $6 - m$ reciprocal complement of the force-controlled subspace, while $\delta\mathbf{x}_f$ is the end-effector infinitesimal twist displacement corresponding to the environment deformation. Hence,

$$\delta\mathbf{x}_v = \mathbf{P}_v \delta\mathbf{x}_{eo}, \quad (9.45)$$

$$\delta\mathbf{x}_f = (\mathbf{I} - \mathbf{P}_v) \delta\mathbf{x}_{eo} = (\mathbf{I} - \mathbf{P}_v) \delta\mathbf{x}_{so}, \quad (9.46)$$

where $\mathbf{P}_v = \mathbf{S}_v \mathbf{S}_v^\dagger$ and \mathbf{S}_v and \mathbf{S}_v^\dagger are defined as in the rigid environment case. Being $\mathbf{P}_v \mathbf{P}_v = \mathbf{P}_v$, the matrix \mathbf{P}_v is a projection matrix that filters out all the end-effector twists (and infinitesimal twist displacements) that are not in the range space of \mathbf{S}_v . Moreover, $\mathbf{I} - \mathbf{P}_v$ is a projection matrix that filters out all the end-effector twists

(and infinitesimal twist displacements) that are in the range space of \mathbf{S}_v . The twists $\mathbf{P}_v \mathbf{v}$ are denoted as *twists of freedom* while the twists $(\mathbf{I} - \mathbf{P}_v) \mathbf{v}$ are denoted as *twists of constraint*.

In the hypothesis of frictionless contact, the interaction wrench between the end-effector and the environment is restricted to a force-controlled subspace defined by the m -dimensional range space of a matrix \mathbf{S}_f , as for the rigid environment case, i. e.,

$$\mathbf{h}_e = \mathbf{S}_f \boldsymbol{\lambda} = \mathbf{h}_s, \quad (9.47)$$

where $\boldsymbol{\lambda}$ is an $m \times 1$ dimensionless vector. Premultiplying both sides of (9.44) by \mathbf{S}_f^\top and using (9.43), (9.45), (9.46), and (9.47) yields

$$\mathbf{S}_f^\top \delta\mathbf{x}_{eo} = \mathbf{S}_f^\top \mathbf{C} \mathbf{S}_f \boldsymbol{\lambda},$$

where the identity $\mathbf{S}_f^\top \mathbf{P}_v = \mathbf{0}$ has been exploited. Therefore, the following elastic model can be found

$$\mathbf{h}_e = \mathbf{S}_f \boldsymbol{\lambda} = \mathbf{K}' \delta\mathbf{x}_{eo}, \quad (9.48)$$

where $\mathbf{K}' = \mathbf{S}_f (\mathbf{S}_f^\top \mathbf{C} \mathbf{S}_f)^{-1} \mathbf{S}_f^\top$ is the positive-semidefinite stiffness matrix corresponding to the partially constrained interaction.

If the compliance matrix \mathbf{C} is adopted as a weighting matrix for the computation of \mathbf{S}_f^\dagger , then \mathbf{K}' can be expressed as

$$\mathbf{K}' = \mathbf{P}_f \mathbf{K}, \quad (9.49)$$

where $\mathbf{P}_f = \mathbf{S}_f \mathbf{S}_f^\dagger$. Being $\mathbf{P}_f \mathbf{P}_f = \mathbf{P}_f$, matrix \mathbf{P}_f is a projection matrix that filters out all the end-effector wrenches that are not in the range space of \mathbf{S}_f .

The compliance matrix for the partially constrained interaction cannot be computed as the inverse of \mathbf{K}' , since this matrix is of rank $m < 6$. However, using (9.46), (9.43), and (9.47), the following equality can be found

$$\delta\mathbf{x}_f = \mathbf{C}' \mathbf{h}_e,$$

where the matrix

$$\mathbf{C}' = (\mathbf{I} - \mathbf{P}_v) \mathbf{C}, \quad (9.50)$$

of rank $6 - m$, is positive semidefinite. If the stiffness matrix \mathbf{K} is adopted as a weighting matrix for the computation of \mathbf{S}_v^\dagger , then the matrix \mathbf{C}' has the noticeable expression $\mathbf{C}' = \mathbf{C} - \mathbf{S}_v (\mathbf{S}_v^\top \mathbf{K} \mathbf{S}_v)^{-1} \mathbf{S}_v^\top$, showing that \mathbf{C}' is symmetric.

9.3.3 Task Specification

An interaction task can be assigned in terms of a desired end-effector wrench \mathbf{h}_d and twist \mathbf{v}_d . In order to be consistent with the constraints, these vectors must lie in the force- and velocity-controlled subspaces, respectively. This can be guaranteed by specifying vectors λ_d and \mathbf{v}_d and computing \mathbf{h}_d and \mathbf{v}_d as

$$\mathbf{h}_d = \mathbf{S}_f \lambda_d, \quad \mathbf{v}_d = \mathbf{S}_v \mathbf{v}_d,$$

where \mathbf{S}_f and \mathbf{S}_v have to be suitably defined on the basis of the geometry of the task, and so that invariance with respect to the choice of the reference frame and change of physical units is guaranteed.

Many robotic tasks have a set of orthogonal reference frames in which the task specification is very easy and intuitive. Such frames are called *task frames* or *compliance frames*. An interaction task can be specified by assigning a desired force/torque or a desired linear/angular velocity along/about each of the frame axes. The desired quantities are known as *artificial constraints* because they are imposed by the controller; these constraints, in the case of rigid contact, are complementary to those imposed by the environment, known as *natural constraints*.

Some examples of task frame definition and task specification are given below.

Peg-in-Hole

The goal of this task is to push the peg into the hole while avoiding wedging and jamming. The peg has two degrees of motion freedom, hence the dimension of the velocity-controlled subspace is $6 - m = 2$, while the dimension of the force-controlled subspace is $m = 4$. The task frame can be chosen as shown in Fig. 9.3 and the task can be achieved by assigning the following desired forces and torques:

- Zero forces along the x_t and y_t axes
- Zero torques about the x_t and y_t axes,

Fig. 9.3 Insertion of a cylindrical peg into a hole

and the desired velocities:

- A nonzero linear velocity along the z_t -axis
- An arbitrary angular velocity about the z_t -axis.

The task continues until a *large* reaction force in the z_t direction is measured, indicating that the peg has hit the bottom of the hole, not represented in the figure. Hence, the matrices \mathbf{S}_f and \mathbf{S}_v can be chosen as

$$\mathbf{S}_f = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \mathbf{S}_v = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix},$$

where the columns of \mathbf{S}_f have the dimensions of wrenches and those of \mathbf{S}_v have the dimensions of twists, defined in the task frame, and they transform accordingly when changing the reference frame. The task frame can be chosen either attached to the end-effector or to the environment.

Turning a Crank

The goal of this task is turning a crank with an idle handle. The handle has two degrees of motion freedom, corresponding to the rotation about the z_t -axis and to the rotation about the rotation axis of the crank. Hence the dimension of the velocity-controlled subspace is $6 - m = 2$, while the dimension of the force-controlled subspace is $m = 4$. The task frame can be assumed as in the Fig. 9.4, attached to the crank. The task can be achieved by assigning the following desired forces and torques:

- Zero forces along the x_t and z_t axes
- Zero torques about the x_t and y_t axes.

and the following desired velocities:

Fig. 9.4 Turning a crank with an idle handle

- A nonzero linear velocity along the y_t -axis
- An arbitrary angular velocity about the z_t -axis.

Hence, the matrices \mathbf{S}_f and \mathbf{S}_v can be chosen as

$$\mathbf{S}_f = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \mathbf{S}_v = \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix},$$

referred to the task frame. In this case, the task frame is fixed with respect to the crank, but in motion with respect both the end-effector frame (fixed to the handle) and to the base frame of the robot. Hence, the matrices \mathbf{S}_f and \mathbf{S}_v are time variant when referred either to the end-effector frame or to the base frame.

Sliding a Block on a Planar Elastic Surface

The goal of this task is to slide a prismatic block over a planar surface along the x_t -axis, while pushing with a given force against the elastic planar surface. The object has three degrees of motion freedom, hence the dimension of the velocity-controlled subspace is $6 - m = 3$ while the dimension of the force-controlled subspace is $m = 3$. The task frame can be chosen attached to the environment, as shown in Fig. 9.5, and the task can be achieved by assigning the desired velocities:

- A nonzero velocity along the x_t -axis
- A zero velocity along the y_t -axis
- A zero angular velocity about the z_t -axis,

and the desired forces and torques:

- A nonzero force along the z_t -axis
- Zero torques about the x_t and y_t axes.

Fig. 9.5 Sliding of a prismatic object on a planar elastic surface

Hence, the matrices \mathbf{S}_f and \mathbf{S}_v can be chosen as

$$\mathbf{S}_f = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}, \quad \mathbf{S}_v = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The elements of the 6×6 stiffness matrix \mathbf{K}' , corresponding to the partially constrained interaction of the end-effector with the environment, are all zero except those of the 3×3 principal minor \mathbf{K}'_m formed by rows 3, 4, 5 and columns 3, 4, 5 of \mathbf{K}' , which can be computed as

$$\mathbf{K}'_m = \begin{pmatrix} c_{3,3} & c_{3,4} & c_{3,5} \\ c_{4,3} & c_{4,4} & c_{4,5} \\ c_{5,3} & c_{5,4} & c_{5,5} \end{pmatrix}^{-1},$$

where $c_{i,j} = c_{j,i}$ are the elements of the compliance matrix \mathbf{C} .

General Contact Model

The task frame concept has proven to be very useful for the specification of a variety of practical robotic tasks. However, it only applies to task geometries with limited complexity, for which separate control modes can be assigned independently to three pure translational and three pure rotational directions along the axes of a single frame. For more complex situations, as in the case of multiple-point contact, a task frame may not exist and more complex contact models have to be adopted. A possible solution is represented by the *virtual contact manipulator* model, where each individual contact is modeled by a virtual kinematic chain between the manipulated object and the environment, giving the manipulated object (instantaneously) the same motion freedom as the contact. The velocities and force kinematics of the parallel manipulator, formed by the virtual manipulators of all individual contacts, can be derived using the standard kinematics procedures of real manipulators and allow the construction of bases for the twist and wrench spaces of the total motion constraint.

A more general approach, known as *constraint-based task specification* opens up new applications involving complex geometries and/or the use of multiple sensors (force/torque, distance, visual sensors) for controlling different directions in space simultaneously. The concept of task frame is extended to that of multiple *feature frames*. Each of the feature frames makes it possible to model part of the task geometry using translational and rotational directions along the axes of a frame; also, part of the constraints is specified in each

Fig.9.6a,b Estimation of orientation error: **(a)** velocity-based approach, **(b)** force-based approach

of the feature frames. The total model and the total set of constraints are achieved by collecting the partial task and constraints descriptions, each expressed in the individual feature frames.

9.3.4 Sensor-Based Contact Model Estimation

The task specification relies on the definition of the velocity-controlled subspace and of the force-controlled subspace assuming that an accurate model of the contact is available all the time. On the other hand, in most practical implementations, the selection matrices S_f and S_v are not exactly known, however many interaction control strategies turn out to be rather robust against modeling errors. In fact, to cope reliably with

these situations is exactly why force control is used. The robustness of the force controller increases if the matrices S_f and S_v can be continuously updated, using motion and/or force measurements, during task execution.

In detail, a nominal model is assumed to be available; when the contact situation evolves differently from what the model predicts, the measured and predicted motion and force will begin to deviate. These small incompatibilities can be measured and can then be used to adapt the model online, using algorithms derived from classical state-space *prediction-correction* estimators such as the Kalman filter.

Figure 9.6 reports an example of error between nominal and measured motion and force variables, typical of a two-dimensional contour-following task. The orientation of the contact normal changes if the environment is not planar. Hence an angular error θ appears between the nominal contact normal, aligned to the y_t -axis of the task frame (the frame with axes x_t and y_t), and the real contact normal, aligned to the y_r -axis of the real task frame (the frame with axes x_r and y_r). This angle can be estimated with either velocity or force measurements only:

- **Velocity-based approach:** the executed linear velocity v , which is tangent to the real contour (aligned to the x_r -axis), does not completely lie along the x_t -axis, but has a small component v_{y_t} along the y_t -axis. The orientation error θ can then be approximated by $\theta = \tan^{-1}(v_{y_t}/v_{x_t})$.
- **Force-based approach:** the measured (ideal) contact force f does not completely lie along the nominal normal direction, aligned to the y_t -axis, but has a small component f_{x_t} along the x_t -axis. The orientation error θ can then be approximated by $\theta = \tan^{-1}(f_{x_t}/f_{y_t})$.

The velocity-based approach is disturbed by mechanical compliance in the system; the force-based approach is disturbed by contact friction.

9.4 Hybrid Force/Motion Control

The aim of hybrid force/motion control is to split up simultaneous control of both end-effector motion and contact forces into two separate decoupled subproblems. In the following, the main control approaches in the hybrid framework are presented for the cases of both rigid and compliant environments.

9.4.1 Acceleration-Resolved Approach

As for the case of motion control, the acceleration-resolved approach is aimed at decoupling and lineariz-

ing the nonlinear robot dynamics at the acceleration level, via an inverse dynamics control law. In the presence of interaction with the environment, a complete decoupling between the force- and velocity-controlled subspaces is sought. The basic idea is that of designing a model-based *inner control loop* to compensate for the nonlinear dynamics of the robot manipulator and decouple the force and velocity subspaces; hence an *outer control loop* is designed to ensure disturbance rejection and tracking of the desired end-effector force and motion.

Rigid Environment

In the case of a rigid environment, the external wrench can be written in the form $\mathbf{h}_e = \mathbf{S}_f \boldsymbol{\lambda}$. The force multiplier $\boldsymbol{\lambda}$ can be computed from (9.2) by multiplying both sides of (9.2) by the weighted pseudo-inverse \mathbf{S}_f^\dagger with weight $\boldsymbol{\Lambda}^{-1}(\mathbf{q})$ and using the time derivative of the last equality (9.35). This yields

$$\boldsymbol{\lambda} = \mathbf{S}_f^\dagger(\mathbf{q}) [\mathbf{h}_e - \boldsymbol{\mu}(\mathbf{q}, \dot{\mathbf{q}})] + \boldsymbol{\Lambda}_f(\mathbf{q}) \dot{\mathbf{S}}_f^T \mathbf{v}_e, \quad (9.51)$$

where $\boldsymbol{\Lambda}_f(\mathbf{q}) = (\mathbf{S}_f^T \boldsymbol{\Lambda}^{-1} \mathbf{S}_f)^{-1}$ and $\boldsymbol{\mu}(\mathbf{q}, \dot{\mathbf{q}}) = \boldsymbol{\Gamma} \dot{\mathbf{q}} + \boldsymbol{\eta}$. Replacing again (9.51) into (9.2) gives

$$\boldsymbol{\Lambda}(\mathbf{q}) \dot{\mathbf{v}}_e + \mathbf{S}_f \boldsymbol{\Lambda}_f(\mathbf{q}) \dot{\mathbf{S}}_f^T \mathbf{v}_e = \mathbf{N}_f(\mathbf{q}) [\mathbf{h}_e - \boldsymbol{\mu}(\mathbf{q}, \dot{\mathbf{q}})], \quad (9.52)$$

with $\mathbf{N}_f = \mathbf{I} - \mathbf{S}_f \mathbf{S}_f^\dagger$. Notice that $\mathbf{N}_f \mathbf{N}_f = \mathbf{N}_f$ and $\mathbf{N}_f \mathbf{S}_f = \mathbf{0}$, hence the 6×6 matrix \mathbf{N}_f is a projection matrix that filters out all the end-effector wrenches lying in the range of \mathbf{S}_f . These correspond to wrenches that tend to violate the constraints. Equation (9.52) represents a set of six second-order differential equations whose solution, if initialized on the constraints, automatically satisfy (9.29) at all times.

The reduced-order dynamics of the constrained system is described by $6 - m$ second-order equations that are obtained by premultiplying both sides of (9.52) by the matrix \mathbf{S}_v^T and substituting the acceleration $\dot{\mathbf{v}}_e$ with

$$\dot{\mathbf{v}}_e = \mathbf{S}_v \dot{\mathbf{v}} + \dot{\mathbf{S}}_v \mathbf{v}.$$

The resulting equations are

$$\boldsymbol{\Lambda}_v(\mathbf{q}) \dot{\mathbf{v}} = \mathbf{S}_v^T [\mathbf{h}_e - \boldsymbol{\mu}(\mathbf{q}, \dot{\mathbf{q}}) - \boldsymbol{\Lambda}(\mathbf{q}) \dot{\mathbf{S}}_v \mathbf{v}], \quad (9.53)$$

where

$$\boldsymbol{\Lambda}_v = \mathbf{S}_v^T \boldsymbol{\Lambda} \mathbf{S}_v$$

and the identities (9.38) and

$$\mathbf{S}_v^T \mathbf{N}_f = \mathbf{S}_v^T$$

have been used. Moreover, expression (9.51) can be rewritten as

$$\boldsymbol{\lambda} = \mathbf{S}_f^\dagger(\mathbf{q}) [\mathbf{h}_e - \boldsymbol{\mu}(\mathbf{q}, \dot{\mathbf{q}}) - \boldsymbol{\Lambda}(\mathbf{q}) \dot{\mathbf{S}}_v \mathbf{v}], \quad (9.54)$$

where the identity $\dot{\mathbf{S}}_f^T \mathbf{S}_v = -\mathbf{S}_f^T \dot{\mathbf{S}}_v$ has been exploited.

Equation (9.54) reveals that the force multiplier vector $\boldsymbol{\lambda}$ instantaneously depends also on the applied input wrench \mathbf{h}_e . Hence, by suitably choosing \mathbf{h}_e , it is possible to directly control the m independent components of the end-effector wrench that tend to violate the constraints; these components can be computed from the m

force multipliers through (9.31). On the other hand, the $6 - m$ independent components of the end-effector velocity twist can be controlled through \mathbf{h}_e via (9.53).

An inverse-dynamics *inner control loop* can be designed by choosing the control wrench \mathbf{h}_e as

$$\mathbf{h}_e = \boldsymbol{\Lambda}(\mathbf{q}) \mathbf{S}_v \boldsymbol{\alpha}_v + \mathbf{S}_f \mathbf{f}_\lambda + \boldsymbol{\mu}(\mathbf{q}, \dot{\mathbf{q}}) + \boldsymbol{\Lambda}(\mathbf{q}) \dot{\mathbf{S}}_v \mathbf{v}, \quad (9.55)$$

where $\boldsymbol{\alpha}_v$ and \mathbf{f}_λ are properly designed control inputs.

Substituting (9.55) into (9.53) and (9.51) yields

$$\dot{\mathbf{v}} = \boldsymbol{\alpha}_v,$$

$$\boldsymbol{\lambda} = \mathbf{f}_\lambda,$$

showing that control law (9.55) allows complete decoupling between the force- and velocity-controlled subspaces.

It is worth noticing that, for the implementation of the control law (9.55), the constraint (9.29) as well as (9.40) defining the vector of the configuration variables for the constrained system are not required, provided that the matrices \mathbf{S}_f and \mathbf{S}_v are known or estimated online. In these cases, the task can easily be assigned by specifying a desired force, in terms of the vector $\boldsymbol{\lambda}_d(t)$, and a desired velocity, in terms of the vector $\mathbf{v}_d(t)$; moreover, a force/velocity control is implemented.

The desired force $\boldsymbol{\lambda}_d(t)$ can be achieved by setting

$$\mathbf{f}_\lambda = \boldsymbol{\lambda}_d(t), \quad (9.56)$$

but this choice is very sensitive to disturbance forces, since it contains no force feedback. Alternative choices are

$$\mathbf{f}_\lambda = \boldsymbol{\lambda}_d(t) + \mathbf{K}_{P\lambda} [\boldsymbol{\lambda}_d(t) - \boldsymbol{\lambda}(t)], \quad (9.57)$$

or

$$\mathbf{f}_\lambda = \boldsymbol{\lambda}_d(t) + \mathbf{K}_{I\lambda} \int_0^t [\boldsymbol{\lambda}_d(\tau) - \boldsymbol{\lambda}(\tau)] d\tau, \quad (9.58)$$

where $\mathbf{K}_{P\lambda}$ and $\mathbf{K}_{I\lambda}$ are suitable positive-definite matrix gains. The proportional feedback is able to reduce the force error due to disturbance forces, while the integral action is able to compensate for constant bias disturbances.

The implementation of force feedback requires the computation of the force multiplier $\boldsymbol{\lambda}$ from the measurement of the end-effector wrench \mathbf{h}_e , which can be achieved by using (9.33).

Velocity control is achieved by setting

$$\begin{aligned} \boldsymbol{\alpha}_v = & \dot{\mathbf{v}}_d(t) + \mathbf{K}_{Pv} [\mathbf{v}_d(t) - \mathbf{v}(t)] \\ & + \mathbf{K}_{Iv} \int_0^t [\mathbf{v}_d(\tau) - \mathbf{v}(\tau)] d\tau, \end{aligned} \quad (9.59)$$

where \mathbf{K}_{P_v} and \mathbf{K}_{I_v} are suitable matrix gains. It is straightforward to show that asymptotic tracking of $\mathbf{v}_d(t)$ and $\dot{\mathbf{v}}_d(t)$ is ensured with exponential convergence for any choice of positive-definite matrices \mathbf{K}_{P_v} and \mathbf{K}_{I_v} .

The computation of the vector \mathbf{v} from the available measurements can be achieved using (9.39), where the end-effector twist is computed from joint position and velocity measurements through (9.1).

Equations (9.57) or (9.58) and (9.59) represent the *outer control loop* ensuring *force/velocity* control and disturbance rejection.

When (9.29) and (9.40) are known, the matrices \mathbf{S}_f and \mathbf{S}_v can be computed according to (9.32) and (9.42) and a *force/position* control can be designed by specifying a desired force $\lambda_d(t)$ and a desired position $\mathbf{r}_d(t)$.

Force control can be designed as above, while position control can be achieved by setting

$$\alpha_v = \ddot{\mathbf{r}}_d(t) + \mathbf{K}_{D_r} [\dot{\mathbf{r}}_d(t) - \mathbf{v}(t)] + \mathbf{K}_{P_r} [\mathbf{r}_d(t) - \mathbf{r}(t)] .$$

Asymptotic tracking of $\mathbf{r}_d(t)$, $\dot{\mathbf{r}}_d(t)$ and $\ddot{\mathbf{r}}_d(t)$ is ensured with exponential convergence for any choice of positive-definite matrices \mathbf{K}_{D_r} and \mathbf{K}_{P_r} . The vector \mathbf{r} required for position feedback can be computed from joint position measurements via (9.40).

Compliant Environment

In the case of a compliant environment, according to the decomposition (9.44) of the end-effector displacement, the end-effector twist can be decomposed as

$$\mathbf{v}_e = \mathbf{S}_v \mathbf{v} + \mathbf{C}' \mathbf{S}_f \dot{\lambda} , \quad (9.60)$$

where the first term is a twist of freedom, the second term is a twist of constraint, the vector \mathbf{v} is defined as in (9.42), and \mathbf{C}' is defined in (9.50). Assuming a constant contact geometry and compliance, i.e., $\dot{\mathbf{S}}_v = \mathbf{0}$, $\dot{\mathbf{C}}' = \mathbf{0}$, and $\dot{\mathbf{S}}_f = \mathbf{0}$, a similar decomposition holds in terms of acceleration

$$\dot{\mathbf{v}}_e = \mathbf{S}_v \dot{\mathbf{v}} + \mathbf{C}' \mathbf{S}_f \ddot{\lambda} . \quad (9.61)$$

An inverse-dynamics control law (9.16) can be adopted, resulting in the closed loop (9.17), where α is a properly designed control input.

In view of the acceleration decomposition (9.61), the choice

$$\alpha = \mathbf{S}_v \alpha_v + \mathbf{C}' \mathbf{S}_f f_\lambda \quad (9.62)$$

allows decoupling of the force control from velocity control. In fact, substituting (9.61) and (9.62)

into (9.17) and premultiplying both sides of the resulting equation once by \mathbf{S}_v^\dagger and once by \mathbf{S}_f^\dagger , the following decoupled equations can be derived

$$\dot{\mathbf{v}} = \alpha_v , \quad (9.63)$$

$$\ddot{\lambda} = f_\lambda . \quad (9.64)$$

Hence, by choosing α_v according to (9.59) as for the rigid environment case, asymptotic tracking of a desired velocity $\mathbf{v}_d(t)$ and acceleration $\dot{\mathbf{v}}_d(t)$ is ensured, with exponential convergence. The control input f_λ can be chosen as

$$f_\lambda = \ddot{\lambda}_d(t) + \mathbf{K}_{D_\lambda} [\dot{\lambda}_d(t) - \dot{\lambda}(t)] + \mathbf{K}_{P_\lambda} [\lambda_d(t) - \lambda(t)] , \quad (9.65)$$

ensuring asymptotic tracking of a desired force trajectory $(\lambda_d(t), \dot{\lambda}_d(t), \ddot{\lambda}_d(t))$ with exponential convergence for any choice of positive-definite matrices \mathbf{K}_{D_λ} and \mathbf{K}_{P_λ} .

Differently from the rigid environment case, feedback of $\dot{\lambda}$ is required for the implementation of the force control law (9.65). This quantity could be computed from end-effector wrench measurements \mathbf{h}_e as

$$\dot{\lambda} = \mathbf{S}_f^\dagger \dot{\mathbf{h}}_e .$$

However, since the wrench measurement signal is often noisy, the feedback of $\dot{\lambda}$ is often replaced by

$$\dot{\lambda} = \mathbf{S}_f^\dagger \mathbf{K}' \mathbf{J}(\mathbf{q}) \dot{\mathbf{q}} , \quad (9.66)$$

where joint velocities are measured using tachometers or computed from joint positions via numerical differentiation and \mathbf{K}' is the positive-semidefinite stiffness matrix (9.49) describing the partially constrained interaction. For the computation of (9.66), only knowledge (or an estimate) of \mathbf{K}' is required, and not that of the full stiffness matrix \mathbf{K} . Also, the implementation of the control law (9.62) requires knowledge (or an estimate) of the compliance matrix \mathbf{C}' of the partially constrained interaction and not that of the full compliance matrix \mathbf{C} .

If the contact geometry is known, but only an estimate of the stiffness/compliance of the environment is available, the control law (9.62), with (9.65), may still guarantee the convergence of the force error, if a constant desired force λ_d is assigned. In this case, the control law (9.62) has the form

$$\alpha = \mathbf{S}_v \alpha_v + \widehat{\mathbf{C}}' \mathbf{S}_f f_\lambda ,$$

where $\widehat{\mathbf{C}}' = (\mathbf{I} - \mathbf{P}_v) \widehat{\mathbf{C}}$ and $\widehat{\mathbf{C}}$ is an estimate of the compliance matrix. Hence, (9.63) still holds, while, in lieu of (9.64), the following equality can be found

$$\ddot{\lambda} = \mathbf{L}_f f_\lambda ,$$

where $\mathbf{L}_f = (\mathbf{S}_f^T \mathbf{C} \mathbf{S}_f)^{-1} \mathbf{S}_f^T \hat{\mathbf{C}} \mathbf{S}_f$ is a nonsingular matrix. Thus, the force- and velocity-controlled subspaces remain decoupled and the velocity control law (9.59) does not need to be modified. On the other hand, if the feedback of the time derivative of λ is computed using (9.66), only an estimate $\hat{\lambda}$ can be obtained. Using (9.66), (9.60) and (9.48), the following equality can be found

$$\dot{\hat{\lambda}} = \mathbf{L}_f^{-1} \dot{\lambda}.$$

Therefore, computing the force control law f_λ as in (9.65) with a constant λ_d , $\hat{\lambda}$ in lieu of λ and $\mathbf{K}_{D\lambda} = \mathbf{K}_{D\lambda} \mathbf{I}$, the dynamics of the closed-loop system is

$$\ddot{\lambda} + \mathbf{K}_{D\lambda} \dot{\lambda} + \mathbf{L}_f \mathbf{K}_{P\lambda} \lambda = \mathbf{L}_f \mathbf{K}_{P\lambda} \lambda_d,$$

showing that exponential asymptotic stability of the equilibrium $\lambda = \lambda_d$ can be ensured, also in the presence of the uncertain matrix \mathbf{L}_f , with a suitable choice of the gains $\mathbf{K}_{D\lambda}$ and $\mathbf{K}_{P\lambda}$.

9.4.2 Passivity-Based Approach

The passivity-based approach exploits the passivity properties of the dynamic model of the manipulator, which hold also for the constrained dynamic model (9.2). It can be easily shown that the choice of the matrix $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ that guarantees the skew symmetry of the matrix $\dot{\mathbf{H}}(\mathbf{q}) - 2\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ in the joint space, also makes the matrix $\dot{\mathbf{A}}(\mathbf{q}) - 2\mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})$ skew symmetric. This fundamental property of Lagrangian systems is at the base of passivity-based control algorithms.

Rigid Environment

The control wrench \mathbf{h}_c can be chosen as

$$\begin{aligned} \mathbf{h}_c = & \mathbf{A}(\mathbf{q}) \mathbf{S}_v \dot{\mathbf{v}}_r + \mathbf{\Gamma}'(\mathbf{q}, \dot{\mathbf{q}}) \mathbf{v}_r + (\mathbf{S}_v^\dagger)^T \mathbf{K}_v (\mathbf{v}_r - \mathbf{v}) \\ & + \boldsymbol{\eta}(\mathbf{q}) + \mathbf{S}_f f_\lambda, \end{aligned} \quad (9.67)$$

where $\mathbf{\Gamma}'(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{\Gamma} \mathbf{S}_v + \mathbf{A} \dot{\mathbf{S}}_v$, \mathbf{K}_v is a suitable symmetric and positive-definite matrix, and \mathbf{v}_r and f_λ are properly designed control inputs.

Substituting (9.67) into (9.2) yields

$$\begin{aligned} \mathbf{A}(\mathbf{q}) \mathbf{S}_v \dot{\mathbf{s}}_v + \mathbf{\Gamma}'(\mathbf{q}, \dot{\mathbf{q}}) \mathbf{s}_v + (\mathbf{S}_v^\dagger)^T \mathbf{K}_v \mathbf{s}_v \\ + \mathbf{S}_f (f_\lambda - \lambda) = \mathbf{0}, \end{aligned} \quad (9.68)$$

with $\dot{\mathbf{s}}_v = \dot{\mathbf{v}}_r - \dot{\mathbf{v}}$ and $\mathbf{s}_v = \mathbf{v}_r - \mathbf{v}$, showing that the closed-loop system remains nonlinear and coupled.

Premultiplying both sides of (9.68) by the matrix \mathbf{S}_v , the following expression for the reduced-order dynamics is achieved

$$\mathbf{A}_v(\mathbf{q}) \dot{\mathbf{s}}_v + \mathbf{\Gamma}_v(\mathbf{q}, \dot{\mathbf{q}}) \mathbf{s}_v + \mathbf{K}_v \mathbf{s}_v = \mathbf{0}, \quad (9.69)$$

with $\mathbf{\Gamma}_v = \mathbf{S}_v^T \mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}}) \mathbf{S}_v + \mathbf{S}_v^T \mathbf{A}(\mathbf{q}) \dot{\mathbf{S}}_v$; it can easily be shown that the skew symmetry of the matrix $\dot{\mathbf{A}}(\mathbf{q}) - 2\mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})$ implies that the matrix $\dot{\mathbf{A}}_v(\mathbf{q}) - 2\mathbf{\Gamma}_v(\mathbf{q}, \dot{\mathbf{q}})$ is skew symmetric as well.

On the other hand, premultiplying both sides of (9.68) by the matrix $\mathbf{S}_f^T \mathbf{A}^{-1}(\mathbf{q})$, the following expression for the force dynamics can be found

$$f_\lambda - \lambda = -\mathbf{S}_f^\dagger(\mathbf{q}) \left[\mathbf{\Gamma}'(\mathbf{q}, \dot{\mathbf{q}}) - (\mathbf{S}_v^\dagger)^T \mathbf{K}_v \right] \mathbf{s}_v, \quad (9.70)$$

being \mathbf{S}_f^\dagger the weighted pseudo-inverse of \mathbf{S}_f with weight $\mathbf{A}^{-1}(\mathbf{q})$. The above equation shows that the force multiplier λ instantaneously depends on the control input f_λ but also on the error \mathbf{s}_v in the velocity-controlled subspace.

The asymptotic stability of the reduced-order system (9.69) can be ensured with the choices

$$\dot{\mathbf{v}}_r = \dot{\mathbf{v}}_d + \boldsymbol{\alpha} \Delta \mathbf{v}, \quad (9.71)$$

$$\mathbf{v}_r = \mathbf{v}_d + \boldsymbol{\alpha} \Delta \mathbf{x}_v, \quad (9.72)$$

where $\boldsymbol{\alpha}$ is a positive gain, $\dot{\mathbf{v}}_d$ and \mathbf{v}_d are the desired acceleration and velocity, respectively, $\Delta \mathbf{v} = \mathbf{v}_d - \mathbf{v}$, and

$$\Delta \mathbf{x}_v = \int_0^t \Delta \mathbf{v}(\boldsymbol{\tau}) d\boldsymbol{\tau}.$$

The stability proof is based on the positive-definite Lyapunov function

$$V = \frac{1}{2} \mathbf{s}_v^T \mathbf{A}_v(\mathbf{q}) \mathbf{s}_v + \boldsymbol{\alpha} \Delta \mathbf{x}_v^T \mathbf{K}_v \Delta \mathbf{x}_v,$$

whose time derivative along the trajectories of (9.69),

$$\dot{V} = -\Delta \mathbf{v}^T \mathbf{K}_v \Delta \mathbf{v} - \boldsymbol{\alpha}^2 \Delta \mathbf{x}_v^T \mathbf{K}_v \Delta \mathbf{x}_v,$$

is a definite semi-negative function. Hence, $\Delta \mathbf{v} = \mathbf{0}$, $\Delta \mathbf{x}_v = \mathbf{0}$, and $\mathbf{s}_v = \mathbf{0}$ asymptotically. Therefore, tracking of the desired velocity $\mathbf{v}_d(t)$ is ensured. Moreover, the right-hand side of (9.70) remains bounded and vanishes asymptotically. Hence, tracking of the desired force $\lambda_d(t)$ can be ensured by setting f_λ as for the acceleration-resolved approach, according to the choices (9.56)–(9.58).

Notice that position control can be achieved if a desired position $\mathbf{r}_d(t)$ is assigned for the vector \mathbf{r} in (9.40), provided that the matrices \mathbf{S}_f and \mathbf{S}_v are computed according to (9.32) and (9.42), and the vectors $\dot{\mathbf{v}}_d = \dot{\mathbf{r}}_d$, $\mathbf{v}_d = \dot{\mathbf{r}}_d$, and $\Delta \mathbf{x}_v = \mathbf{r}_d - \mathbf{r}$ are used in (9.71) and (9.72).

Compliant Environment

The control wrench \mathbf{h}_c can be chosen as

$$\mathbf{h}_c = \mathbf{\Lambda}(\mathbf{q})\dot{\mathbf{v}}_r + \mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v}_r + \mathbf{K}_s(\mathbf{v}_r - \mathbf{v}_e) + \mathbf{h}_e + \boldsymbol{\eta}(\mathbf{q}), \quad (9.73)$$

where \mathbf{K}_s is a suitable symmetric positive-definite matrix while \mathbf{v}_r and its time derivative $\dot{\mathbf{v}}_r$ are chosen as

$$\begin{aligned} \mathbf{v}_r &= \mathbf{v}_d + \boldsymbol{\alpha}\Delta\mathbf{x}, \\ \dot{\mathbf{v}}_r &= \dot{\mathbf{v}}_d + \boldsymbol{\alpha}\Delta\dot{\mathbf{v}}, \end{aligned}$$

where $\boldsymbol{\alpha}$ is the positive gain, \mathbf{v}_d and its time derivative $\dot{\mathbf{v}}_d$ are properly designed control inputs, $\Delta\mathbf{v} = \mathbf{v}_d - \mathbf{v}_e$, and

$$\Delta\mathbf{x} = \int_0^t \Delta\mathbf{v} d\tau.$$

Substituting (9.73) into (9.2) yields

$$\mathbf{\Lambda}(\mathbf{q})\dot{\mathbf{s}} + \mathbf{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{s} + \mathbf{K}_s\mathbf{s} = \mathbf{0}, \quad (9.74)$$

with $\dot{\mathbf{s}} = \dot{\mathbf{v}}_r - \dot{\mathbf{v}}_e$ and $\mathbf{s} = \mathbf{v}_r - \mathbf{v}_e$.

The asymptotic stability of system (9.74) can be ensured by setting

$$\mathbf{v}_d = \mathbf{S}_v\mathbf{v}_d + \mathbf{C}'\mathbf{S}_f\dot{\boldsymbol{\lambda}}_d,$$

where $\mathbf{v}_d(t)$ is a desired velocity trajectory and $\boldsymbol{\lambda}_d(t)$ is the desired force trajectory. The stability proof is based on the positive-definite Lyapunov function

$$V = \frac{1}{2}\mathbf{s}^T\mathbf{\Lambda}(\mathbf{q})\mathbf{s} + \boldsymbol{\alpha}\Delta\mathbf{x}^T\mathbf{K}_s\Delta\mathbf{x},$$

whose time derivative along the trajectories of (9.74),

$$\dot{V} = -\Delta\mathbf{v}^T\mathbf{K}_s\Delta\mathbf{v} - \boldsymbol{\alpha}^2\Delta\mathbf{x}^T\mathbf{K}_s\Delta\mathbf{x},$$

is a negative-definite function. Hence, $\Delta\mathbf{v} = \mathbf{0}$ and $\Delta\mathbf{x} = \mathbf{0}$, asymptotically. In the case of constant contact geometry and stiffness, the following equalities hold

$$\begin{aligned} \Delta\mathbf{v} &= \mathbf{S}_v(\mathbf{v}_d - \mathbf{v}) + \mathbf{C}'\mathbf{S}_f(\dot{\boldsymbol{\lambda}}_d - \dot{\boldsymbol{\lambda}}), \\ \Delta\mathbf{x} &= \mathbf{S}_v \int_0^t (\mathbf{v}_d - \mathbf{v}) d\tau + \mathbf{C}'\mathbf{S}_f(\boldsymbol{\lambda}_d - \boldsymbol{\lambda}), \end{aligned}$$

showing that both the velocity and force tracking errors, belonging to reciprocal subspaces, converge asymptotically to zero.

9.4.3 Velocity-Resolved Approach

The acceleration-resolved approach, as well as the passivity-based approach, require modification of the current industrial robot controllers. As for the case of impedance control, if the contact is sufficiently compliant, the closed-loop dynamics of a motion-controlled robot can be approximated by (9.28), corresponding to a velocity-resolved control.

To achieve force and velocity control, according to the end-effector twist decomposition (9.60), the control input \mathbf{v}_r can be chosen as

$$\mathbf{v}_r = \mathbf{S}_v\mathbf{v}_v + \mathbf{C}'\mathbf{S}_f\mathbf{f}_\lambda, \quad (9.75)$$

with

$$\mathbf{v}_v = \mathbf{v}_d(t) + \mathbf{K}_{Iv} \int_0^t [\mathbf{v}_d(\tau) - \mathbf{v}(\tau)] d\tau, \quad (9.76)$$

and

$$\mathbf{f}_\lambda = \dot{\boldsymbol{\lambda}}_d(t) + \mathbf{K}_{p\lambda}[\boldsymbol{\lambda}_d(t) - \boldsymbol{\lambda}(t)], \quad (9.77)$$

where \mathbf{K}_{Iv} and $\mathbf{K}_{p\lambda}$ are suitable symmetric and positive-definite matrix gains. Decoupling between velocity- and force-controlled subspaces and exponential asymptotic stability of the closed-loop system can be proven as for the acceleration-resolved approach. Also, since the force error has second-order dynamics, an integral action can be added to (9.77) to improve the disturbance rejection capabilities, i. e.,

$$\begin{aligned} \mathbf{f}_\lambda &= \dot{\boldsymbol{\lambda}}_d(t) + \mathbf{K}_{p\lambda}[\boldsymbol{\lambda}_d(t) - \boldsymbol{\lambda}(t)] \\ &\quad + \mathbf{K}_{I\lambda} \int_0^t [\boldsymbol{\lambda}_d(\tau) - \boldsymbol{\lambda}(\tau)] d\tau, \end{aligned} \quad (9.78)$$

and the exponential asymptotic stability is guaranteed if the matrices $\mathbf{K}_{p\lambda}$ and $\mathbf{K}_{I\lambda}$ are symmetric and positive definite.

If an estimate $\hat{\mathbf{C}}$ of the stiffness matrix of the environment is used in (9.75), as for the acceleration-resolved approach, the exponential convergence of $\boldsymbol{\lambda}$ to a constant $\boldsymbol{\lambda}_d$ can still be ensured for both (9.77) and (9.78).

In some applications, besides the stiffness matrix, also the geometry of the environment is uncertain. In these cases, a force/motion control law similar to (9.75) can be implemented, without using the selection matrices \mathbf{S}_v and \mathbf{S}_f to separate the force-controlled subspace from the velocity-controlled subspace. The motion control law can be set as in (9.76),

but using full velocity feedback. Also, the force control law can be set as in (9.78), but using full force and moment feedback. That is, both motion control and force control are applied in all directions of the six-dimensional (6-D) space. The resulting control, known as *force control with feedforward motion* or *parallel force/position control* guarantees force regulation at the expense of position errors along the constrained task directions, thanks to the dominance

of the force controller over the position controller ensured by the presence of the integral action on the force error. This approach is tested in the experiments reported in  VIDEO 687 and  VIDEO 691 where the concept of task frame is also exploited. A framework for robotic assembly, where a standard position-based robot controller is integrated with an external controller performing force-controlled skills is presented in  VIDEO 692.

9.5 Conclusions and Further Reading

This chapter has summarized the main approaches to force control in a unifying perspective. However, there are many aspects that have not been considered and that must be carefully taken into account when dealing with interaction robotic tasks. The two major paradigms of force control (impedance and hybrid force/motion control) are based on several simplifying assumptions that are only partially satisfied in practical implementations. In fact, the performance of a force-controlled robotic system depends on the interaction with a changing environment which is very difficult to model and identify correctly. A general contact situation is far from being completely predictable, not only quantitatively, but also qualitatively: the contact configuration can change abruptly, or be of a different type than expected. Hence, the standard performance indices used to evaluate a control system, i. e., stability, bandwidth, accuracy, and robustness, cannot be defined by considering the robotic system alone, as for the case of robot motion control, but must be always referred to the particular contact situation at hand. Also, a classification of all these different situations is not easy, especially in the case of dynamics environments and when the task involves multiple contacts acting in parallel.

Due to the inherent complexity of the force control problem, a large number of research papers on this topic have been published in the past three decades. A description of the state of the art of the first decade is provided in [9.20], whereas the progress of the second decade is surveyed in [9.21] and [9.22]. More recently, two monographs on force control [9.23, 24] have appeared. In the following, a list of references is provided, where more details on the arguments presented in the chapter, as well as topics not covered here, can be found.

9.5.1 Indirect Force Control

The concept of generalized spring and damping for force control in joint coordinates was originally pro-

posed in [9.3] and the implementation discussed in [9.10]. Stiffness control in Cartesian coordinates was proposed in [9.9]. Devices based on the remote center of compliance were discussed in [9.25] for successful mating of rigid parts. The original idea of a mechanical impedance model used for controlling the interaction between the manipulator and the environment is presented in [9.7], and a similar formulation is given in [9.8]. Stability of impedance control was analyzed in [9.26] and the problems of interaction with a stiff environment were considered in [9.27].

Adaptive impedance control algorithms [9.28, 29] have been proposed to overcome uncertainties in the dynamic parameters of the robot manipulator, while robust control schemes can be found in [9.30]. Impedance control has also been used in the hybrid force/motion control framework [9.31].

A reference work on modeling 6-DOF (spatial) stiffness is [9.32], while the properties of spatial compliance have been analyzed in detail in [9.33–35]; a 6-DOF variable compliant wrist was proposed in [9.36], while several studies concerning the construction of programmed compliances, optimized for specific tasks, have been proposed [9.37, 38]. The energy-based approach to derive a spatial impedance was introduced in [9.39], using rotation matrices; various 6-DOF impedance control schemes based on different representations of end-effector orientation, including the unit quaternion, can be found in [9.40]. The quaternion-based formulation is extended to the case of non-block-diagonal stiffness matrix in [9.41]. A rigorous treatment of spatial impedance control in a passivity framework can be found in [9.42].

More recently, impedance control was proposed as an effective approach to enhance safety in applications where humans and robots share the same workspace and may have physical interaction. To this end, the passive compliance of lightweight robots is combined with the active compliance ensured by impedance control [9.43, 44].

9.5.2 Task Specification

The concepts of natural and artificial constraints and of compliance frame were introduced in [9.11]. These ideas have been systematically developed in [9.12, 45] within the *task frame formalism*. Theoretical issues on the reciprocity of generalized force and velocity directions are discussed in [9.46, 47], while invariance in computing the generalized inverse in robotics is addressed in [9.48]. The issue of partially constrained tasks is considered in [9.49], where the models of positive-semidefinite stiffness and compliance matrices are developed. The problem of estimating geometric uncertainties is considered in [9.50, 51], as well as the issue of linking constraint-based task specification with real-time task execution control. This approach is generalized in [9.52], where a systematic constraint-based methodology to specify complex tasks is presented.

9.5.3 Hybrid Force/Motion Control

Early works on force control can be found in [9.10]. The original hybrid force/position control concept was introduced in [9.13], based on the natural and artificial constraint task formulation [9.11]. The explicit inclusion of the manipulator dynamic model was presented in [9.17], and a systematic approach to modeling the interaction with a dynamic environment was developed in [9.53]. The constrained formulation with inverse dynamic controllers is treated in [9.14, 54] in the Cartesian space as well as in [9.15] joint space. The constrained approach was also used in [9.16] with a controller based on linearized equations. The invari-

ance problems pointed out in [9.47] were correctly addressed, among other papers, in [9.46, 55]. Transposition of model-based schemes from unconstrained motion control to constrained cases was accomplished for adaptive control in [9.18, 56, 57] and for robust control in [9.58].

Approaches designed to cope with uncertainties in the environment geometry are the force control with feedforward motion scheme proposed in [9.2] and the parallel force/position control [9.19], based on the concept of dominance of force control on motion control, thanks to the use of an integral action on the force error. A parallel force/position regulator was developed in [9.59]. The integral action for removing steady-state force errors has traditionally been used; its stability was proven in [9.60], while robustness with respect to force measurement delays was investigated in [9.61, 62].

In the absence of force/torque sensors, suitable algorithms can be adopted to estimate the contact force, based, e.g., on disturbance observers [9.63], or on the error of a position control [9.64].

It has generally been recognized that force control may cause unstable behavior during contact with environment. Dynamic models for explaining this phenomenon were introduced in [9.65] and experimental investigations can be found in [9.66] and [9.67]. Moreover, control schemes are usually derived on the assumption that the manipulator end-effector is in contact with the environment and that this contact is not lost. Impact phenomena may occur and deserve careful consideration, and there is a need for global analysis of control schemes including the transition from noncontact to contact situations and vice versa, see e.g., [9.68–70].

10. Redundant Robots

Stefano Chiaverini, Giuseppe Oriolo, Anthony A. Maciejewski

This chapter focuses on redundancy resolution schemes, i.e., the techniques for exploiting the redundant degrees of freedom in the solution of the inverse kinematics problem. This is obviously an issue of major relevance for motion planning and control purposes.

In particular, task-oriented kinematics and the basic methods for its inversion at the velocity (first-order differential) level are first recalled, with a discussion of the main techniques for handling kinematic singularities. Next, different first-order methods to solve kinematic redundancy are arranged in two main categories, namely those based on the optimization of suitable performance criteria and those relying on the augmentation of the task space. Redundancy resolution methods at the acceleration (second-order differential) level are then considered in order to take into account dynamics issues, e.g., torque minimization. Conditions under which a cyclic task motion results in a cyclic joint motion are also discussed; this is a major issue when a redundant manipulator is used to execute a repetitive task, e.g., in industrial applications. The use of kinematic redundancy for fault tolerance is analyzed in detail. Suggestions for further reading are given in a final section.

10.1 Overview

Kinematic redundancy occurs when a robotic manipulator has more degrees of freedom than those strictly required to execute a given task. This means that, in principle, no manipulator is inherently redundant; rather, there are certain tasks with respect to which it may become redundant. Because it is widely recognized that a fully general spatial task consists of following an end-effector motion trajectory requiring six degrees of freedom, a robot arm with seven or more joints is frequently considered as a typical example of an inherently

redundant manipulator. However, even robot arms with fewer degrees of freedom, like conventional six-joint industrial manipulators, may become kinematically redundant for specific tasks, such as simple end-effector positioning without constraints on the orientation.

The motivation for introducing kinematic redundancy in the mechanical structure of a manipulator goes beyond that for using redundancy in traditional engineering design, namely, increasing robustness to faults so as to improve reliability (e.g., redundant processors

or sensors). In fact, endowing robotic manipulators with kinematic redundancy is mainly aimed at increasing dexterity, as is the case with a human arm.

The minimal-complexity approach that characterized early manipulator designs had the objective of minimizing cost and maintenance. For example, this led to the development of selective compliance assembly robot arm (SCARA) robots for pick-and-place operations where products had been designed for assembly, i. e., using a single axis of insertion. However, giving a manipulator the minimum number of joints required to execute its task results in a serious limitation in real-world applications where, in addition to the singularity problem, joint limits or workspace obstacles are present. All of these give rise to forbidden regions in the joint space that must be avoided during operation, thus requiring a carefully structured (and static) workspace where the motion of the manipulator can be planned in advance; this is the typical situation for workcells in traditional industrial applications.

On the other hand, the presence of additional degrees of freedom besides those strictly required to execute the task allows motions of the manipulator that

do not displace the end effector (the so-called self-motions or internal motions); this implies that the same task at the end-effector level can be executed in several ways at the joint level, giving the possibility of avoiding the forbidden regions and ultimately resulting in a more versatile mechanism. Such a feature is key to allowing operation in unstructured or dynamically vary-

Fig. 10.2 The 7-DOF Mitsubishi PA-10 manipulator

Fig. 10.4 A 5-finger hand by Schunk

ing environments that characterize advanced industrial applications and service robotics scenarios.

In practice, if properly managed, the increased dexterity characterizing kinematically redundant robots may allow them to not only avoid singularities, joint limits, and workspace obstacles, but also to minimize torque/energy over a given task, ultimately meaning that the robotic manipulator can achieve a higher degree of autonomy.

The biological archetype of a kinematically redundant manipulator is the human arm, which, not surprisingly, also inspires the terminology used to characterize the structure of serial-chain manipulators. In fact, the human arm has three degrees of freedom at the *shoulder*, one degree of freedom at the *elbow* and three degrees of freedom at the *wrist*. The available redundancy can be easily verified by locking one's wrist, e.g., on a table and moving the elbow while keeping the shoulder still. The kinematic arrangement of the human arm has been replicated in a number of robots often termed as *human-arm-like* manipulators. This family

of 7-DOF (degree of freedom) manipulators includes the DLR (Deutsches Zentrum für Luft- und Raumfahrt) Lightweight Robot (Fig. 10.1) and the Mitsubishi PA-10 robot (Fig. 10.2). An example of an 8-DOF robot is the DEXTER by Scienza Machinale (Fig. 10.3). Manipulators with a larger number of joints are often called *hyperredundant* robots, and include many snake-like robots described in the literature.

The use of two or more robotic structures to execute a task (as in the case of multifingered hands, humanoid mockups or cooperating manipulators, Figs. 10.4–10.7, respectively) also gives rise to kinematic redundancy. Redundant mechanisms also include vehicle-manipulator systems (Fig. 10.8); in this case, however, the possible presence of nonholonomic constraints on the

Fig. 10.6 The NASA (National Aeronautics and Space Administration) Robonaut

Fig. 10.8 A huge vehicle-manipulator system by KUKA Aktiengesellschaft

motion of the base must be properly taken into account in order to determine the actual degree of redundancy.

Although the realization of a kinematically redundant structure raises a number of issues from the point of view of mechanical design, this chapter focuses

on redundancy resolution schemes, i. e., techniques for exploiting the redundant degrees of freedom in the solution of the inverse kinematics problem. This is an issue of major relevance for motion planning and control purposes.

10.2 Task-Oriented Kinematics

The relationship between the variables representing the configuration of an articulated manipulator and those describing an assigned task in the appropriate space can be established at the position, velocity or acceleration level. In particular, consideration of the first-order task kinematics inevitably results in discussion of the task Jacobian matrix, which is central to many redundancy resolution techniques.

10.2.1 Task-Space Formulation

A manipulator consists of a chain of rigid bodies articulated by joints. If q_i denotes the variable characterizing the relative displacement of body i with respect to body $i-1$, the vector $\mathbf{q} = (q_1 \dots q_N)^T$ uniquely describes the configuration of an N -joint serial-chain manipulator. Joint i may be either prismatic or revolute, in which case q_i measures the relative translation or rotation of the attached links, respectively.

While the manipulator is naturally described and actuated in the *joint space*, its operation is conveniently specified in terms of the vector $\mathbf{t} = (t_1 \dots t_M)^T$, which typically defines the location of the manipulator end-effector in a suitably defined *task space*. In the general case, it is of dimension $M = 6$ and \mathbf{t} is chosen so that its first three components represent the position of the end effector, while its last three components represent a minimal description of the end-effector orientation (such as Euler angles or the roll-pitch-yaw representation), i. e.,

$$\mathbf{t} = [p_x \quad p_y \quad p_z \quad \alpha \quad \beta \quad \gamma]^T.$$

Typically, one has $N \geq M$, so that the joints can provide at least the number of degrees of freedom required for the end-effector task. If $N > M$ strictly, the manipulator is *kinematically redundant*.

The relationship between the joint-space coordinate vector \mathbf{q} and the task-space coordinate vector \mathbf{t} is expressed by the *direct kinematics* equation

$$\mathbf{t} = \mathbf{k}_t(\mathbf{q}), \quad (10.1)$$

where \mathbf{k}_t is a nonlinear vector function.

Task Jacobian and Geometric Jacobian

It is useful to consider the *first-order differential kinematics* [10.1]

$$\dot{\mathbf{t}} = \mathbf{J}_t(\mathbf{q}) \dot{\mathbf{q}}, \quad (10.2)$$

that can be obtained by differentiating (10.1) with respect to time. In (10.2), $\dot{\mathbf{t}}$ is the task-space velocity vector, $\dot{\mathbf{q}}$ is the joint-space velocity vector, and $\mathbf{J}_t(\mathbf{q}) = \partial \mathbf{k}_t / \partial \mathbf{q}$ is the $M \times N$ *task Jacobian* matrix (also called the *analytic Jacobian*).

Remarkably, the components of $\dot{\mathbf{t}}$ relative to the end-effector orientation express the rate of change of the parameters characterizing the adopted minimal representation; they are not the components of the angular velocity vector of the end-effector. Indeed, denoting by \mathbf{v}_N the 3×1 translational velocity vector and by $\boldsymbol{\omega}_N$ the 3×1 angular velocity vector of the end-effector, and defining the end-effector spatial velocity \mathbf{v}_N as

$$\mathbf{v}_N = \begin{pmatrix} \mathbf{v}_N \\ \boldsymbol{\omega}_N \end{pmatrix}, \quad (10.3)$$

the following relationship holds

$$\dot{\mathbf{t}} = \mathbf{T}(\mathbf{t}) \mathbf{v}_N, \quad (10.4)$$

where \mathbf{T} is an $M \times 6$ transformation matrix that is a function of \mathbf{t} only. In the case of $M = 6$, the transformation matrix \mathbf{T} takes the form

$$\mathbf{T} = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{R} \end{pmatrix}, \quad (10.5)$$

where \mathbf{I} and $\mathbf{0}$ are, respectively, the identity and null matrix of proper dimensions, and \mathbf{R} is a 3×3 matrix that specifically depends on the minimal representation used to describe the end-effector orientation.

For a given manipulator, the mapping

$$\mathbf{v}_N = \mathbf{J}(\mathbf{q}) \dot{\mathbf{q}} \quad (10.6)$$

relates a joint-space velocity to the corresponding end-effector velocity through the $6 \times N$ *geometric Jacobian*

matrix \mathbf{J} . The geometric Jacobian matrix is of major concern in the kinematic analysis of a manipulator because it allows description of the motion capabilities of the end-effector (in terms of its free rigid-body spatial velocity) as a result of the velocity commands at the joints in the current configuration. As a matter of fact, if $\mathbf{J}_{P_i}\dot{q}_i$ denotes the contribution of \dot{q}_i to \mathbf{v}_N , \mathbf{z}_{i-1} is the unit vector of the axis of joint i and $\mathbf{r}_{i-1,e}$ is the vector expressing the position of the end effector frame with respect to the joint i frame, it is

$$\mathbf{J}_{P_i} = \begin{cases} \mathbf{z}_{i-1} & \text{if joint } i \text{ is prismatic} \\ \mathbf{z}_{i-1} \times \mathbf{r}_{i-1,e} & \text{if joint } i \text{ is revolute,} \end{cases}$$

whereas if $\mathbf{J}_{O_i}\dot{q}_i$ denotes the contribution of \dot{q}_i to $\boldsymbol{\omega}_N$, it is

$$\mathbf{J}_{O_i} = \begin{cases} \mathbf{0} & \text{if joint } i \text{ is prismatic} \\ \mathbf{z}_{i-1} & \text{if joint } i \text{ is revolute.} \end{cases}$$

By comparing (10.2), (10.4), and (10.6), the relation between the geometric Jacobian and the task Jacobian can be found as

$$\mathbf{J}_t(\mathbf{q}) = \mathbf{T}(\mathbf{t}) \mathbf{J}(\mathbf{q}). \quad (10.7)$$

Second-Order Differential Kinematics

While the first-order differential kinematics (10.2) relates task-space to joint-space velocities, further differentiation with respect to time provides an analogous relationship between accelerations

$$\ddot{\mathbf{t}} = \mathbf{J}_t(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{J}}_t(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}. \quad (10.8)$$

This equation is also known as the *second-order differential kinematics*.

10.2.2 Singularities

In this section the occurrence of singular configurations is considered to properly analyze their effect on inverse kinematics solutions.

Representation and Kinematic Singularities

A robot configuration \mathbf{q} is *singular* if the task Jacobian matrix \mathbf{J}_t is rank-deficient there. Considering the role of \mathbf{J}_t in (10.2) and (10.8), it is easy to realize that at a singular configuration it is impossible to generate end-effector task velocities or accelerations in certain directions. Further insight can be gained by looking at (10.7), which indicates that a singularity may be due to a loss of rank of the transformation matrix \mathbf{T} and/or of the geometric Jacobian matrix \mathbf{J} .

Rank deficiencies of \mathbf{T} are only related to the mathematical relationship established by \mathbf{R} between the angular velocity vector of the end-effector and the components of $\dot{\mathbf{t}}$ relative to the end-effector orientation; because the expression of \mathbf{R} depends on the adopted minimal representation of the orientation, a configuration at which \mathbf{T} is singular is then referred to as a *representation singularity*. Remarkably, any minimal description of the end-effector orientation experiences the occurrence of representation singularities. Furthermore, a given configuration may or may not yield a representation singularity depending on which description of orientation is used.

A representation singularity is not directly related to the true motion capabilities of the manipulator structure, which can instead be inferred by the analysis of the geometric Jacobian matrix. Rank deficiencies of \mathbf{J} are in fact related to loss of mobility of the manipulator end-effector; indeed, end-effector velocities exist in this case that are unfeasible for any velocity commanded at the joints. A configuration at which \mathbf{J} is singular is referred to as a *kinematic singularity*.

Because this chapter focuses on the inversion of the task differential kinematics (10.2) and (10.8), in the following the task Jacobian matrix and its singularities (which include representation and kinematic singularities) are studied in detail. The case $N \geq M$ is considered, which encompasses conventional as well as redundant manipulators.

Singular Value Decomposition of the Jacobian

To analyze the linear mapping (10.2), the *singular value decomposition* (SVD) of the Jacobian matrix is adopted; remarkably, this powerful numerical tool is the sole reliable method to compute the rank of a matrix and to study near-singular linear mappings. The classic *Golub–Reinsch* algorithm [10.2], which is the most efficient and numerically stable algorithm to compute the SVD of an arbitrary matrix, may however be computationally demanding in view of real-time applications. A faster algorithm that takes advantage of the nature of robotic matrix calculations has been proposed [10.3]; this makes it possible to improve real-time kinematic control techniques.

The SVD of the task Jacobian matrix can be written in the form

$$\mathbf{J}_t = \mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^T = \sum_{i=1}^M \sigma_i \mathbf{u}_i \mathbf{v}_i^T, \quad (10.9)$$

where \mathbf{U} is the $M \times M$ orthonormal matrix of the output singular vectors \mathbf{u}_i , \mathbf{V} is the $N \times N$ orthonormal matrix of the input singular vectors \mathbf{v}_i , and $\boldsymbol{\Sigma} = (\mathbf{S} \mathbf{0})$ is the $M \times N$ matrix whose $M \times M$ diagonal submatrix \mathbf{S}

contains the singular values σ_i of the matrix \mathbf{J}_t . It is worth noting that the SVD is a well-behaved function of its matrix argument; therefore, the singular values and associated subspaces do not change radically in the neighborhood of the current configuration. Letting $\text{rank}(\mathbf{J}_t) = R$, the following hold

$$\begin{aligned}\sigma_1 &\geq \sigma_2 \geq \dots \geq \sigma_R > \sigma_{R+1} = \dots = 0, \\ \mathcal{R}(\mathbf{J}_t) &= \text{span}\{\mathbf{u}_1, \dots, \mathbf{u}_R\}, \\ \mathcal{N}(\mathbf{J}_t) &= \text{span}\{\mathbf{v}_{R+1}, \dots, \mathbf{v}_N\}.\end{aligned}$$

If the task Jacobian is full-rank ($R = M$), all the singular values are nonzero, the range space of \mathbf{J}_t is the entire \mathbb{R}^M , and the null space of \mathbf{J}_t has dimension $N - M$. In a singular configuration, $R < M$; thus, the last $M - R$ singular values are zero, the range space of \mathbf{J}_t is an R -dimensional subspace of \mathbb{R}^M , and the dimension of the null space of \mathbf{J}_t increases to $N - R$. An interpretation of this from a kinematic viewpoint is presented in the following.

Feasible Velocities. At each configuration, the range space of \mathbf{J}_t is the set of task-space velocities that can be obtained as a result of all possible joint-space velocities $\dot{\mathbf{q}}$; therefore, it constitutes the so-called subspace of *feasible velocities* for the end-effector task. A basis for $\mathcal{R}(\mathbf{J}_t)$ is given by the first R output singular vectors; accordingly, the effect of a singularity is to decrease the dimension of the range space of \mathbf{J}_t that corresponds to a reduction of the space of feasible velocities.

Null-Space Velocities. At each configuration, the null space of \mathbf{J}_t is the set of joint-space velocities that yield zero task velocity; these are thus shortly called *null-space velocities*. A basis for $\mathcal{N}(\mathbf{J}_t)$ is given by the $N - R$ last input singular vectors, which represent independent linear combinations of the velocities at each joint. From this viewpoint, the effect of a singularity is to increase the dimension of the null space of \mathbf{J}_t by introducing a further independent linear combination of joint velocities that produces a zero task velocity.

According to (10.2) and (10.9), a joint velocity along the i -th input singular vector results in a task velocity that lies along the i -th output singular vector

$$\forall \rho \in \mathbb{R} \quad \dot{\mathbf{q}} = \rho \mathbf{v}_i \quad \Rightarrow \quad \mathbf{t} = \sigma_i \rho \mathbf{u}_i.$$

Thus, the i -th singular value of \mathbf{J}_t can be viewed as a gain factor relating motion along the \mathbf{v}_i direction of the joint velocity space to the resulting motion along the \mathbf{u}_i direction of the task velocity space. When a singularity is approached, the R -th singular value σ_R tends to zero and the task velocity produced by a fixed joint

velocity along \mathbf{v}_R is decreased proportionally. At a singular configuration, the joint-space velocity along \mathbf{v}_R belongs to the null-space velocities and task velocities along \mathbf{u}_R become unfeasible for the manipulator.

In the generic case, the joint-space velocity $\dot{\mathbf{q}}$ is an arbitrary linear combination of individual joint velocities with nonzero components along all the \mathbf{v}_i . Its effect can be analyzed by combining the single effects of the above components. Remarkably, the components of $\dot{\mathbf{q}}$ in the null space of \mathbf{J}_t produce a change in the configuration of the manipulator without affecting its task velocity. This can be exploited to achieve additional goals – such as obstacle or singularity avoidance – in addition to the realization of a desired task motion, and constitutes the core of redundancy resolution approaches.

Distance from Singularities

Clearly, the effect of a singularity is experienced not only at the singular configuration itself but also in its neighborhood (Sect. 10.3.2). For this reason, it is important to be able to characterize the distance from singularities through suitable measures; these can then be exploited to counteract undesirable effects.

Because each singularity is associated with a reduction in the rank of \mathbf{J}_t , one conceptually simple possibility in the case of a square Jacobian matrix ($M = N$) is to compute its determinant. A generalization of this idea that works also for nonsquare Jacobians is the *manipulability measure* [10.4], defined as

$$\mu = \sqrt{|\mathbf{J}_t \mathbf{J}_t^T|}.$$

It can be recognized that the manipulability measure is equal to the product of the singular values of \mathbf{J}_t , i.e.,

$$\mu = \prod_{i=1}^M \sigma_i,$$

and thus its zeros coincide with the singularities.

Another possible measure of distance from a singular configuration is the *condition number* of the Jacobian matrix [10.5], defined as

$$\kappa = \frac{\sigma_1}{\sigma_M}.$$

The condition number has values ranging from 1, at configurations where all the singular values are equal, to ∞ , at singular configurations. Note that when $\kappa = 1$ the end effector has the same motion capability in all task space directions because all the singular values are equal – i.e., the arm is at an *isotropic configuration* – whereas at a singularity it loses mobility in some task-space direction.

An even more direct measure of the distance from singular configurations is the *smallest singular value* of the Jacobian matrix [10.5], i. e.,

$$\sigma_{\min} = \sigma_M .$$

A computationally light estimate of the smallest singular value can be obtained either via numerical methods [10.3, 6, 7] or based on a kinematic analysis of the robot structure [10.8].

10.3 Inverse Differential Kinematics

In order to accomplish a task, a proper joint motion must be commanded to the manipulator; therefore, it is necessary to derive mathematical relations that allow one to compute joint-space variables corresponding to the assigned task-space variables. This is the objective of the inverse kinematics problem.

The inverse kinematics problem can be solved by inverting the direct kinematics equation (10.1), the first-order differential kinematics (10.2) or the second-order differential kinematics (10.8). If the task is time-varying (i. e., if a desired trajectory $\mathbf{t}(t)$ is assigned), it is convenient to solve the differential kinematic relationships because these represent linear equations using the task Jacobian matrix [10.9].

10.3.1 The General Solution

Under the assumption that the manipulator is kinematically redundant (i. e., $M < N$), one solution of (10.2) or (10.8) can be expressed by resorting to the pseudoinverse \mathbf{J}_t^\dagger of the task Jacobian matrix [10.1, 10]; this is the unique matrix satisfying the Moore–Penrose conditions [10.11–13]

$$\begin{aligned} \mathbf{J}_t \mathbf{J}_t^\dagger \mathbf{J}_t &= \mathbf{J}_t , \\ \mathbf{J}_t^\dagger \mathbf{J}_t \mathbf{J}_t^\dagger &= \mathbf{J}_t^\dagger , \\ (\mathbf{J}_t \mathbf{J}_t^\dagger)^T &= \mathbf{J}_t \mathbf{J}_t^\dagger , \\ (\mathbf{J}_t^\dagger \mathbf{J}_t)^T &= \mathbf{J}_t^\dagger \mathbf{J}_t . \end{aligned} \quad (10.10)$$

If \mathbf{J}_t is low-rectangular and full-rank, its pseudoinverse can be expressed as

$$\mathbf{J}_t^\dagger = \mathbf{J}_t^T (\mathbf{J}_t \mathbf{J}_t^T)^{-1} . \quad (10.11)$$

If \mathbf{J}_t is square, expression (10.11) reduces to the standard inverse matrix.

The general solution of (10.2) can be written as

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{t}} + (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \dot{\mathbf{q}}_0 . \quad (10.12)$$

It must be noted that the manipulability measure may remain constant even in the presence of variations of either the condition number or the smallest singular value of \mathbf{J}_t . On the other hand, because the smallest singular value changes more radically near singularities than the other singular values, it dominates the behavior of the determinant and the condition number of the Jacobian matrix; therefore, the most effective measure of distance from singular configurations is the smallest singular value of \mathbf{J}_t [10.5].

Here, $\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t$ represents the orthogonal projection matrix into the null space of \mathbf{J}_t , and $\dot{\mathbf{q}}_0$ is an arbitrary joint-space velocity; the second part of the solution is therefore a null-space velocity. Equation (10.12) provides all least-squares solution to the end-effector task constraint (10.2), i. e., it minimizes $\|\dot{\mathbf{t}} - \mathbf{J}_t \dot{\mathbf{q}}\|$. In particular, if \mathbf{J}_t is low-rectangular and full-rank, all joint velocities in the form (10.12) exactly realize the assigned task velocity. By acting on $\dot{\mathbf{q}}_0$, one can still obtain different joint velocities that give the same end-effector task velocity; therefore, as will be discussed later in detail, solutions in the form of (10.12) are typically used to represent redundancy resolution techniques.

The particular solution obtained by setting $\dot{\mathbf{q}}_0 = 0$ in (10.12),

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{t}} , \quad (10.13)$$

provides the least-squares solution of (10.2) with minimum norm, and is known as the *pseudoinverse solution*. In terms of the inverse differential kinematics problem, the least-squares property quantifies the accuracy of the end-effector task realization, while the minimum norm property may be relevant for the feasibility of the joint-space velocities.

As for the second-order kinematics (10.8), its least-squares solutions can be expressed in the general form

$$\ddot{\mathbf{q}} = \mathbf{J}_t^\dagger (\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t \dot{\mathbf{q}}) + (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \ddot{\mathbf{q}}_0 , \quad (10.14)$$

where $\ddot{\mathbf{q}}_0$ is an arbitrary joint-space acceleration. As above, choosing $\ddot{\mathbf{q}}_0 = 0$ in (10.14) gives the minimum-norm acceleration solution

$$\ddot{\mathbf{q}} = \mathbf{J}_t^\dagger (\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t \dot{\mathbf{q}}) . \quad (10.15)$$

10.3.2 Singularity Robustness

We now investigate the kinematics aspects involved in the first-order inverse mappings (10.12) and (10.13)

with respect to the handling of singularities. With reference to the SVD of \mathbf{J}_t in (10.9), let us consider the following decomposition of the matrix \mathbf{J}_t^\dagger

$$\mathbf{J}_t^\dagger = \mathbf{V} \boldsymbol{\Sigma}^\dagger \mathbf{U}^T = \sum_{i=1}^R \frac{1}{\sigma_i} \mathbf{v}_i \mathbf{u}_i^T, \quad (10.16)$$

where, as above, R denotes the rank of the task Jacobian matrix. Analogously to (10.9), the following hold

$$\begin{aligned} \sigma_1 &\geq \sigma_2 \geq \dots \geq \sigma_R > \sigma_{R+1} = \dots = 0, \\ \mathcal{R}(\mathbf{J}_t^\dagger) &= \mathcal{N}^\perp(\mathbf{J}_t) = \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_R\}, \\ \mathcal{N}(\mathbf{J}_t^\dagger) &= \mathcal{R}^\perp(\mathbf{J}_t) = \text{span}\{\mathbf{u}_{R+1}, \dots, \mathbf{u}_M\}. \end{aligned}$$

Notice that, if the Jacobian matrix is full-rank, the range space of \mathbf{J}_t^\dagger is an M -dimensional subspace of \mathbb{R}^N and the null space of \mathbf{J}_t^\dagger is trivial. In a singular configuration ($R < M$), the range space of \mathbf{J}_t^\dagger is an R -dimensional subspace of \mathbb{R}^N , and an $M - R$ -dimensional null space of \mathbf{J}_t^\dagger exists.

The range space of \mathbf{J}_t^\dagger is the set of joint-space velocities $\dot{\mathbf{q}}$ that can be obtained via the inverse kinematic mapping (10.13) as a result of all possible task velocities $\dot{\mathbf{t}}$. Because these $\dot{\mathbf{q}}$ belong to the orthogonal complement of the null space of \mathbf{J}_t , the pseudoinverse solution (10.13) satisfies the least-squares condition, as expected.

The null space of \mathbf{J}_t^\dagger is the set of the task velocities $\dot{\mathbf{t}}$ that yield null joint-space velocity in the current configuration; these $\dot{\mathbf{t}}$ belong to the orthogonal complement of the space of feasible task velocities. Therefore, one effect of the pseudoinverse solution (10.13) is to filter out the unfeasible components of the commanded task velocity while allowing exact tracking of the feasible components; this is related to the minimum-norm property.

If the assigned task velocity is aligned with \mathbf{u}_i , the corresponding joint-space velocity – computed via (10.13) – is obtained along \mathbf{v}_i modulated by the factor $1/\sigma_i$. When a singularity is approached, the R -th singular value tends to zero and a fixed task velocity command along \mathbf{u}_R requires joint-space velocities along \mathbf{v}_R that grow unboundedly in proportion to the factor $1/\sigma_R$. At the singular configuration, the \mathbf{u}_R direction becomes unfeasible for the task variables and \mathbf{v}_R adds to the null-space velocities of the arm.

According to the above, two main problems are inherently related to the basic inverse differential kinematics solution (10.13), namely:

- At near-singular configurations, excessive joint-space velocities may result, due to the component of $\dot{\mathbf{t}}$ along the direction which becomes unfeasible at the singularity.

- At the singular configuration, discontinuity of the joint-space solution is experienced if $\dot{\mathbf{t}}$ has a non-null unfeasible component.

The same is obviously true for the complete inverse solution (10.12).

Both the above problems are of major concern for kinematic control of manipulators, where the computed joint-space velocities must actually be executed by the robot arm. This has motivated the development of modified inverse differential mappings, so as to ensure proper behavior of the manipulator throughout its workspace independent of the configuration of the robot. A reasonable approach is to preserve the mapping (10.13) far from singularities and to set up local modifications of it only inside a region enclosing the singular configuration; the definition of the region depends on a suitable measure of distance from the singularity, while the modified mapping must ensure feasible and continuous joint velocities.

Modification of the Planned Trajectory

One way to tackle the problem of singularities is to act at the planning level by either designing trajectories that do not incur in unavoidable singularities or assigning task-space motion commands that are feasible for the robot arm. However, these solutions rely on perfect task planning and cannot be used in real-time sensory control applications, in which motion commands are generated online.

Because singularities are a function of configuration and not workspace location, in general, it is not possible to avoid singularities by restricting the workspace trajectory of the manipulator. There do exist cases where avoidance of singular configurations at the motion planning level is relatively simple, e.g., when dealing with those associated with workspace boundary such as the elbow singularity of an anthropomorphic arm. However, this approach may be difficult for those singularities, like the wrist one, that may occur everywhere in the workspace.

Another possibility is to perform a joint-space interpolation when the planned trajectory is close to a singularity [10.14]; however, this may cause large errors in tracking the originally assigned task-space motion.

Acting in the task space, a method based on time-scale transformation is presented in [10.15], which slows down the manipulator's motion when a singularity is approached; this technique, however, fails at the singularity.

Because a task-space robot control system must be able to guide the motion of the manipulator safely through singularities, considerable research effort has been devoted to the derivation of well-defined and

continuous inverse kinematic mappings instead of the above ad hoc approaches.

Removal of Dependent Rows or Columns of the Jacobian Matrix

The first requirement of solution (10.13) is the availability of a general algorithm to compute the pseudoinverse of \mathbf{J}_t also when the Jacobian is singular. Several techniques presented in the literature can be arranged in this framework; they consist either in removing the unfeasible end-effector reference components [10.16] or in using nonsingular blocks of the Jacobian matrix [10.10]. The main problem with this type of solution is the specification of the directions of unfeasible velocities in a systematic way and the need to have smooth transitions between the usual inverse kinematic algorithm and the algorithms used close to the singularities.

A systematic procedure to compute the pseudoinverse of the Jacobian matrix can be devised by taking advantage of a kinematic analysis of the manipulator structure because for many manipulators it is possible to identify and describe classes of singular configurations in suitably defined link-fixed frames. This approach has been demonstrated for a six-degree-of-freedom elbow geometry in [10.17, 18].

As for the continuity of the solution across a singularity, it must be observed that, while the singular vectors change very little in the neighborhood of the singularity, the term

$$\frac{1}{\sigma_M} \mathbf{v}_M \mathbf{u}_M^T \dot{\mathbf{i}}$$

suddenly disappears from (10.16) when R becomes less than M at the singular configuration.

One possibility to avoid this problem is to make

$$\mathbf{u}_M^T \dot{\mathbf{i}} \approx 0$$

in the neighborhood of the singularity, which means avoiding commanding task velocities along the direction that becomes unfeasible at the singular configuration. This would require some method for efficiently computing the singular subspace associated with near-zero singular value(s) as described in the upcoming section on numerical filtering.

Independently from the assigned $\dot{\mathbf{i}}$, continuity of the pseudoinverse solution can be ensured by treating the manipulator as singular in a suitably defined region around each singularity through a modified Jacobian $\bar{\mathbf{J}}_t$, so that $M - R$ extra degrees of freedom are available [10.17–19]; these can be used without significantly affecting the end-effector velocity, because the modified Jacobian $\bar{\mathbf{J}}_t$ approximates \mathbf{J}_t inside the region.

The described approach is difficult to generalize for multiple singularities. For the typical anthropomorphic geometry of industrial manipulators, however, only the wrist singularity is of primary concern because it may occur everywhere in the workspace, while the elbow and shoulder singularities are naturally characterized in the task space and thus can be avoided during planning.

Regularization/Damped Least-Squares Technique

The use of the damped least-squares technique in the inverse differential kinematics problem has been independently proposed in [10.9, 20]. The method corresponds to solving the optimization problem

$$\min_{\dot{\mathbf{q}}} (\|\dot{\mathbf{i}} - \mathbf{J}_t \dot{\mathbf{q}}\|^2 + \lambda^2 \|\dot{\mathbf{q}}\|^2), \quad (10.17)$$

which results in a solution $\dot{\mathbf{q}}$ that minimizes the end-effector tracking error from the set of all joint velocities that do not exceed $\|\dot{\mathbf{q}}\|$. Here, $\lambda \in \mathbb{R}$ is the damping factor that represents the trade-off between the least-squares and the minimum-norm properties. When λ is zero, the solution to (10.17) and (10.13) become identical.

The solution to (10.17) can be written in two equivalent forms

$$\dot{\mathbf{q}} = \mathbf{J}_t^T (\mathbf{J}_t \mathbf{J}_t^T + \lambda^2 \mathbf{I})^{-1} \dot{\mathbf{i}}, \quad (10.18)$$

$$\dot{\mathbf{q}} = (\mathbf{J}_t^T \mathbf{J}_t + \lambda^2 \mathbf{I})^{-1} \mathbf{J}_t^T \dot{\mathbf{i}}. \quad (10.19)$$

The computational load of (10.18) is lower than that of (10.19), because usually $N \geq M$. In the remainder, we will refer to the damped least-squares solution as

$$\dot{\mathbf{q}} = \mathbf{J}_t^* (\mathbf{q}) \dot{\mathbf{i}}, \quad (10.20)$$

whenever explicit specification of the computation used is not essential.

Condition (10.17) implies consideration of accuracy and feasibility at the same time when choosing the joint-space velocity required to match the given $\dot{\mathbf{i}}$. In this regard it is essential to suitably select the value to be assigned to the damping factor: small values of λ give accurate solutions but low robustness to the occurrence of singular and near-singular configurations; high values of λ result in low tracking accuracy even when a feasible and accurate solution would be possible.

In the framework of singular value decomposition, the solution (10.20) can be written as

$$\dot{\mathbf{q}} = \sum_{i=1}^R \frac{\sigma_i}{\sigma_i^2 + \lambda^2} \mathbf{v}_i \mathbf{u}_i^T \dot{\mathbf{i}}. \quad (10.21)$$

Remarkably, we have

$$\begin{aligned}\mathcal{R}(\mathbf{J}_t^*) &= \mathcal{R}(\mathbf{J}_t^\dagger) = \mathcal{N}^\perp(\mathbf{J}_t) \\ &= \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_R\}, \\ \mathcal{N}(\mathbf{J}_t^*) &= \mathcal{N}(\mathbf{J}_t^\dagger) = \mathcal{R}^\perp(\mathbf{J}_t) \\ &= \text{span}\{\mathbf{u}_{R+1}, \dots, \mathbf{u}_M\}.\end{aligned}$$

As with \mathbf{J}_t^\dagger , if the Jacobian matrix is full-rank, the range space of \mathbf{J}_t^* is an M -dimensional subspace of \mathbb{R}^N and the null space of \mathbf{J}_t^* is trivial; in a singular configuration, the range space of \mathbf{J}_t^* is an R -dimensional subspace of \mathbb{R}^N , and an $M - R$ -dimensional null space of \mathbf{J}_t^* exists.

It is clear that, with respect to the pure least-squares solution (10.13), in (10.21) the components for which $\sigma_i \gg \lambda$ are little influenced by the damping factor, because in this case

$$\frac{\sigma_i}{\sigma_i^2 + \lambda^2} \approx \frac{1}{\sigma_i}.$$

On the other hand, when a singularity is approached, the smallest singular value tends to zero while the associated component of the solution is driven to zero by the factor σ_i/λ^2 ; this progressively reduces the joint velocity required to achieve near-degenerate components of the commanded $\dot{\mathbf{i}}$. At the singularity, the solutions (10.20) and (10.13) behave identically as long as the remaining singular values are significantly larger than the damping factor. One can show that the maximum gain factor of $1/(2\lambda)$ relating the task velocity component along \mathbf{u}_i to the resulting joint velocity along \mathbf{v}_i occurs when $\sigma_i = \lambda$.

Selection of the Damping Factor. According to above, λ determines the degree of approximation introduced with respect to the pure least-squares solution given by the pseudoinverse. An optimal choice for λ requires consideration of the smallest non-null singular value experienced along the given trajectory and of the minimum damping needed to ensure feasible joint velocities.

To achieve good performance in the entire manipulator's workspace the use of a configuration-varying damping factor has been proposed [10.9]. The natural choice is to adjust λ as a function of some measure of distance from the singularity at the current configuration of the robot arm. Far from singular configurations feasible joint velocities are obtained; thus the accuracy requirement prevails and low damping must be used. Close to a singularity, task velocity commands along the unfeasible directions give large joint velocities and the accuracy requirement must be relaxed; in these cases, high damping is needed.

A first proposal was to adjust the damping factor as a function of the manipulability measure [10.9]. Because a more effective measure of distance from singular configurations is the smallest singular value of the Jacobian matrix [10.5], its use has been considered later for building a variable damping factor.

If an estimate $\tilde{\sigma}_M$ of the smallest singular value is available, the following choice for the damping factor can be adopted [10.21]

$$\lambda^2 = \begin{cases} 0 & \text{when } \tilde{\sigma}_M \geq \varepsilon \\ \left[1 - \left(\frac{\tilde{\sigma}_M}{\varepsilon}\right)^2\right] \lambda_{\max}^2 & \text{otherwise,} \end{cases} \quad (10.22)$$

which ensures continuity and good shaping of the solution. In (10.22), ε defines the size of the singular region, in which damping is used, and λ_{\max} sets the maximum value of the damping factor, which occurs just at the singularity.

Numerical Filtering. As can be recognized from (10.21), the damping factor affects the accuracy of the solution along each end-effector velocity component; however, the sole unfeasible direction is responsible for the (possible) loss of tracking ability. To overcome this problem, selective filtering of the end-effector velocity components was proposed in [10.6]. The method can be generalized as follows; if estimates $\tilde{\mathbf{u}}_i$ of the output singular vectors associated with the $M - K$ smallest singular values – which give the components to become unfeasible – are available, the solution can be written in the form

$$\dot{\mathbf{q}} = \mathbf{J}_t^T \left(\mathbf{J}_t \mathbf{J}_t^T + \lambda^2 \mathbf{I} + \beta^2 \sum_{i=K+1}^M \tilde{\mathbf{u}}_i \tilde{\mathbf{u}}_i^T \right)^{-1} \dot{\mathbf{i}}, \quad (10.23)$$

where β provides the largest contribution to damping only along the unfeasible components. This solution is an approximation to applying a greater selective filtering to the near singular components, i. e.,

$$\begin{aligned}\dot{\mathbf{q}} &\approx \sum_{i=1}^K \frac{\sigma_i}{\sigma_i^2 + \lambda^2} \mathbf{v}_i \mathbf{u}_i^T \dot{\mathbf{i}} \\ &\quad + \sum_{i=K+1}^R \frac{\sigma_i}{\sigma_i^2 + \lambda^2 + \beta^2} \mathbf{v}_i \mathbf{u}_i^T \dot{\mathbf{i}},\end{aligned} \quad (10.24)$$

where the quality of the approximation is based on the accuracy of the estimates of $\tilde{\mathbf{u}}$ in (10.23). Notice that $K \leq R$; nevertheless, a nonzero value of λ is kept to guarantee satisfactory conditioning of the mapping (10.23) even for incorrect estimates of the output singular vectors.

Similarly, additional damping can be provided to the joint-space velocity components given by the in-

put singular vectors associated to the smallest singular values, since they are close to becoming the null-space velocities [10.22]. The solution can be generalized in the form

$$\dot{\mathbf{q}} = \left(\mathbf{J}_t^T \mathbf{J}_t + \lambda^2 \mathbf{I} + \beta^2 \sum_{i=K+1}^N \tilde{\mathbf{v}}_i \tilde{\mathbf{v}}_i^T \right)^{-1} \mathbf{J}_t^T \dot{\mathbf{t}}, \quad (10.25)$$

where β provides the largest contribution to damping only along the $N - K$ estimated null-space velocity components $\tilde{\mathbf{v}}_i$. Once again, this solution is an approximation to applying a greater selective filtering to the near singular components, i. e.,

$$\begin{aligned} \dot{\mathbf{q}} \approx & \sum_{i=1}^K \frac{\sigma_i}{\sigma_i^2 + \lambda^2} \mathbf{v}_i \mathbf{u}_i^T \dot{\mathbf{t}} \\ & + \sum_{i=K+1}^R \frac{\sigma_i}{\sigma_i^2 + \lambda^2 + \beta^2} \mathbf{v}_i \mathbf{u}_i^T \dot{\mathbf{t}}, \end{aligned} \quad (10.26)$$

where the quality of the approximation is based on the accuracy of the estimates $\tilde{\mathbf{v}}_i$ in (10.25). Also in this case a nonzero value of λ is kept to guarantee satisfactory conditioning of the mapping (10.25) even for incorrect estimates of the input singular vectors.

Comparison of (10.26) with (10.24) shows that, in the case of accurate estimate of the singular vectors, the solutions (10.23) and (10.25) behave identically.

10.3.3 Joint Trajectory Reconstruction

When solving the inverse kinematics problem at the first-order differential level, one obtains the joint velocity profile $\dot{\mathbf{q}}(t)$ that corresponds to an assigned end-effector task velocity profile $\dot{\mathbf{t}}(t)$; however, the robot motion controller needs reference position trajectories in addition to the velocity references for the joints. The reconstruction of the joint-position profile from the joint-velocity profile obtained from an end-effector task velocity profile $\dot{\mathbf{t}}(t)$ realizes a kinematic inversion that can be seen as an *inverse kinematics algorithm*.

If the joint-velocity profile were completely specified (e.g., by its analytical expression) the corresponding joint-position profile could be obtained from time integration

$$\mathbf{q}(t) = \mathbf{q}(t_0) + \int_{t_0}^t \dot{\mathbf{q}}(\tau) d\tau. \quad (10.27)$$

However, digital implementation of the robot control system makes it more likely that a discrete-time sequence of samples $\dot{\mathbf{q}}_k$ of the computed joint velocities at the time instants t_k will be available, i. e.,

$$\dot{\mathbf{q}}_k = \dot{\mathbf{q}}(t_k).$$

For this reason, a discrete-time numerical approximation of the continuous-time integral (10.27) must be suitably devised.

Accurate discrete-time approximations of a continuous-time integral usually require a trade-off between the complexity of the interpolating algorithm and the length of the time step. In real-time applications, such as robot motion control, high-order interpolation results in large finite-time delays that degrade the dynamic performance of the control loop. This time delay can be reduced by suitably shortening the time step; in fact, if the time step is sufficiently short even a low-order interpolation may give acceptable accuracy of the numerical integration. It is typical to use first-order interpolation, i. e., an Euler forward rectangular rule that transforms the integral (10.27) into

$$\mathbf{q}_k = \mathbf{q}_0 + \sum_{h=0}^{k-1} \dot{\mathbf{q}}_h \Delta t, \quad (10.28)$$

where Δt is the time step. Equation (10.28) is usually written in the more effective recursive form

$$\mathbf{q}_k = \mathbf{q}_{k-1} + \dot{\mathbf{q}}_{k-1} \Delta t.$$

Closed-Loop Inverse Kinematics (CLIK)

No matter what kind of interpolation is used, the small though unavoidable error suffered at each numerical integration step accumulates, leading to long-term drifting of the reconstructed profile from the exact joint-position profile. Another source of error affecting any integral reconstruction method is the possible uncertainty in the initial value of the joint position.

Algorithmic solutions that overcome these problems are based on the use of a feedback correction term; these are termed *closed-loop inverse kinematics* (CLIK) algorithms [10.23]. Considering, e.g., the case of first-order kinematics, the joint velocity at the k -th time instant is computed as (compare with (10.12))

$$\begin{aligned} \dot{\mathbf{q}}_k = & \mathbf{J}_t^\dagger(\mathbf{q}_k) \{ \dot{\mathbf{t}}_k + \mathbf{K} [\mathbf{t}_k - \mathbf{t}_t(\mathbf{q}_k)] \} \\ & + \left[\mathbf{I} - \mathbf{J}_t^\dagger(\mathbf{q}_k) \mathbf{J}_t(\mathbf{q}_k) \right] \dot{\mathbf{q}}_{0k}, \end{aligned} \quad (10.29)$$

where \mathbf{K} is a constant positive-definite gain matrix.

Second-order CLIK algorithms are also available that solve for joint positions, velocities, and accelerations [10.24, 25]. The CLIK approach was originally proposed in [10.26] and [10.27] based on the Jacobian transpose in lieu of the pseudoinverse, which provides remarkable computational savings and provides inherent singularity handling capabilities [10.28].

10.4 Redundancy Resolution via Optimization

For a kinematically redundant manipulator, the inverse kinematics problem admits an infinite number of solutions, so that a criterion to select one of them is needed. In this section we consider the problem of redundancy resolution via optimization at the first-order differential kinematics level. Before discussing algorithmic schemes for computing joint velocities, we provide a short review of possible performance criteria.

10.4.1 Performance Criteria

The availability of degrees of freedom in excess of those strictly needed to execute a given task can be used to improve the value of performance criteria during the motion. These criteria may depend on the robot joint configuration only, or also involve velocities and/or accelerations.

Among the additional objectives that can be pursued by defining a suitable criterion, arguably the most popular is singularity avoidance. In fact, one of the original motivations for introducing kinematic redundancy was to increase the size of the workspace the manipulator could reach without being in a singular configuration (*unavoidable* singularities) for achieving general motion trajectory tracking tasks. A discussion of avoidable and unavoidable singularities in redundant manipulators can be found in [10.29]. If the assigned end-effector task does not pass through unavoidable singularities, it is in principle always possible to compute a joint trajectory along which the task Jacobian \mathbf{J}_t is continuously full-rank. To this end, possible performance criteria are the configuration-dependent functions introduced in Sect. 10.2.2 that characterize the distance from singularities, i.e., the manipulability measure, the condition number, and the smallest singular value of \mathbf{J}_t . Maximizing (or keeping as large as possible) these functions during the motion is a reasonable plan in order to avoid singular configurations during the motion.

Because kinematic inversion can produce arbitrarily large joint velocities in the vicinity of singular configurations, a conceptually different possibility is to minimize the norm of the joint velocity generated by the redundancy resolution scheme. However, this approach guarantees singularity avoidance only if such a norm is minimized in an integral sense along the motion of the manipulator. Local minimization of the norm [10.10] does not lead to singularity avoidance in any practical sense [10.29].

Redundancy can be also used to keep the manipulator linkage away from undesired regions of the joint space, for example, mechanical joint limits that are typically present in robot manipulators may be avoided by

minimizing the cost function [10.30]

$$\mathbf{H}(\mathbf{q}) = \frac{1}{2} \sum_{i=1}^N \left(\frac{q_i - q_{i,\text{mid}}}{q_{i,\text{max}} - q_{i,\text{min}}} \right)^2,$$

where $[q_{i,\text{min}}, q_{i,\text{max}}]$ is the available range for joint i and $q_{i,\text{mid}}$ is its midpoint. Another interesting application is obstacle avoidance, which can be enforced by minimizing suitable *artificial potential* functions defined on the basis of the image of the obstacle region in the configuration space [10.31, 32].

Many other performance criteria have been proposed in the literature; some of them are mentioned in Sects. 10.5 and 10.8.

10.4.2 Local Optimization

The simplest form of local optimization is represented by the pseudoinverse solution (10.13), which provides the joint velocity with the minimum norm among those that realize the task constraint. Clearly, the joint movement generated by this locally optimal solution does not provide global velocity minimization along the entire manipulator motion. This means that, despite the local minimization of joint velocities, singularity avoidance is not guaranteed [10.29].

Another possibility is to use the general solution (10.12), choosing the arbitrary joint velocity $\dot{\mathbf{q}}_0$ in the direction of the antigradient of a scalar configuration-dependent performance criteria $\mathbf{H}(\mathbf{q})$ that one would like to minimize

$$\dot{\mathbf{q}}_0 = -k_{\mathbf{H}} \nabla \mathbf{H}(\mathbf{q}), \quad (10.30)$$

where $k_{\mathbf{H}}$ is a scalar step size and $\nabla \mathbf{H}(\mathbf{q})$ denotes the gradient of \mathbf{H} at the current joint configuration. This leads to the following redundancy resolution scheme [10.30]

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{t}} - k_{\mathbf{H}} (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \nabla \mathbf{H}(\mathbf{q}). \quad (10.31)$$

Because its second term is the projection of the antigradient of \mathbf{H} in the null space of the task Jacobian, the above expression is reminiscent of the projected gradient method for constrained minimization [10.33]. In particular, it can be shown [10.34] that the inverse kinematic solution (10.31) minimizes the complete quadratic function

$$L(\mathbf{q}, \dot{\mathbf{q}}) = \frac{1}{2} \dot{\mathbf{q}}^T \dot{\mathbf{q}} + k_{\mathbf{H}} \dot{\mathbf{q}}^T \nabla \mathbf{H}(\mathbf{q})$$

at the current configuration \mathbf{q} . Thus, (10.31) represents a natural trade-off between the unconstrained local

minimization of the performance criteria \mathbf{H} (which would lead to choose $\dot{\mathbf{q}} = -k_{\mathbf{H}} \nabla \mathbf{H}(\mathbf{q})$) and the satisfaction of constraint (10.2) by a minimum-norm joint velocity.

The choice of the step size $k_{\mathbf{H}}$ is critical for the performance of the redundancy resolution scheme (10.31). In particular, a small value of the step size may slow down the minimization of the performance criteria, but on the other hand a large value may even lead to an increase of \mathbf{H} (recall that the antigradient is the *local* direction of maximum decrease). In practice, one may use a simplified *line search* technique such as Armijo's rule [10.33] to identify at each configuration an appropriate value of $k_{\mathbf{H}}$ in a reasonable time.

10.4.3 Global Optimization

The main advantage of the redundancy resolution scheme (10.31) is its simplicity: if the computation of $\nabla \mathbf{H}(\mathbf{q})$ and $k_{\mathbf{H}}$ is efficient, such a scheme is a realistic option for real-time kinematic inversion. Its disadvantage is to be found in the local nature of the optimization

process, which can lead to unsatisfactory performance over long tasks, for example, use of (10.31) with $\mathbf{H} = -\mu$ (the manipulability measure) will perform better than the simple pseudoinverse solution, but still cannot guarantee singularity avoidance.

It is therefore natural to consider the possibility of selecting $\dot{\mathbf{q}}_0$ in (10.12) so as to minimize integral criteria of the form

$$\int_{t_i}^{t_f} \mathbf{H}(\mathbf{q}) \, dt .$$

defined over the duration $[t_i, t_f]$ of the entire task (e.g., the integral of manipulability along the motion). Unfortunately, the solution of this problem (naturally formulated within the framework of calculus of variations) may not exist, and, in general, admits no closed form. One way to make the problem solvable is to include a quadratic form in the joint velocities or accelerations inside the integral. However, this is more easily done at the second-order kinematic level (Sect. 10.5).

10.5 Redundancy Resolution via Task Augmentation

Another approach to redundancy resolution consists of augmenting the task vector so as to tackle additional objectives expressed as constraints. In this section, we review the basic task augmentation techniques for solving the first-order differential kinematics (10.2).

10.5.1 Extended Jacobian

The extended Jacobian technique, proposed by *Bailieul* [10.35] and later revisited by *Chang* [10.36], enforces an appropriate number of functional constraints to be fulfilled along with the original end-effector task so as to identify a single solution among the infinite ones that are compatible with the end-effector task.

Let us consider an objective function $g(\mathbf{q})$ to be optimized and let also $\mathbf{N}_{\mathbf{J}_t}(\mathbf{q})$ be a matrix spanning the null space of \mathbf{J}_t at a nonsingular configuration \mathbf{q} , e.g.,

$$\mathbf{N}_{\mathbf{J}_t} = \mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t .$$

It can be recognized that, for a given t_0 , if \mathbf{q}_0 is a configuration at which the function $g(\mathbf{q})$ is at an extreme under the constraint $t_0 = \mathbf{k}_t(\mathbf{q}_0)$, one has

$$\left. \frac{\partial g(\mathbf{q})}{\partial \mathbf{q}} \right|_{\mathbf{q}=\mathbf{q}_0} \mathbf{N}_{\mathbf{J}_t}(\mathbf{q}_0) = \mathbf{0}^T . \quad (10.32)$$

If the Jacobian \mathbf{J}_t has full rank M , then $\mathbf{N}_{\mathbf{J}_t}$ has rank $N - M$; therefore, (10.32) yields a set of $N - M$ inde-

pendent constraints that can be written in vector form as

$$\mathbf{h}(\mathbf{q}) = \mathbf{0} ;$$

for example, these can be obtained by taking the scalar product of the gradient $\partial g(\mathbf{q}) / \partial \mathbf{q}$ by each of the $N - M$ vectors constituting a base of the null space of \mathbf{J}_t , i. e.,

$$\mathbf{h}(\mathbf{q}) = \left(\frac{\partial g(\mathbf{q})}{\partial \mathbf{q}} (\mathbf{v}_{M+1}(\mathbf{q}) \dots \mathbf{v}_N(\mathbf{q})) \right)^T .$$

At this point, the condition (10.32) implies that the equation

$$\begin{pmatrix} \mathbf{k}_t(\mathbf{q}_0) \\ \mathbf{h}(\mathbf{q}_0) \end{pmatrix} = \begin{pmatrix} t_0 \\ \mathbf{0} \end{pmatrix}$$

is satisfied.

For motion starting from t_0 with \mathbf{q}_0 that tracks a trajectory $\mathbf{t}(t)$ by keeping $g(\mathbf{q})$ extremized at each time one has

$$\begin{pmatrix} \mathbf{k}_t(\mathbf{q}(t)) \\ \mathbf{h}(\mathbf{q}(t)) \end{pmatrix} = \begin{pmatrix} \mathbf{t}(t) \\ \mathbf{0} \end{pmatrix} .$$

By differentiating both sides with respect to time one obtains

$$\left(\frac{\mathbf{J}_t(\mathbf{q})}{\frac{\partial \mathbf{h}(\mathbf{q})}{\partial \mathbf{q}}} \right) \dot{\mathbf{q}} = \begin{pmatrix} \dot{\mathbf{t}} \\ \mathbf{0} \end{pmatrix}, \quad (10.33)$$

where the matrix premultiplying the vector $\dot{\mathbf{q}}$ is square and is called the *extended Jacobian* \mathbf{J}_{ext} .

Therefore, if the initial configuration \mathbf{q}_0 extremizes $g(\mathbf{q})$ and provided that \mathbf{J}_{ext} does not become singular, the time integral of the inverse mapping

$$\dot{\mathbf{q}} = \mathbf{J}_{\text{ext}}^{-1}(\mathbf{q}) \begin{pmatrix} \dot{\mathbf{t}} \\ 0 \end{pmatrix} \quad (10.34)$$

tracks the assigned end-effector trajectory $\dot{\mathbf{t}}(t)$ propagating joint configurations that extremize $g(\mathbf{q})$.

The extended Jacobian method has a major advantage over pseudoinverse techniques of the form (10.13) in that it is *cyclic* (Sect. 10.6). Moreover, solution (10.34) can be made equivalent to (10.12) via suitable choice of the vector $\dot{\mathbf{q}}_0$ [10.35, 37]. One relative disadvantage is its performance near algorithmic singularities (Sect. 10.5.3).

10.5.2 Augmented Jacobian

Another approach, the so-called task-space augmentation, introduces a constraint task to be fulfilled along with the end-effector task; then, an augmented Jacobian matrix is set-up whose inverse gives the sought joint velocity solution. The concept of task-space augmentation has been independently introduced by *Sciavicco* and *Siciliano* [10.28, 38, 39] and *Egeland* [10.40] and later revisited by *Seraji* in the framework of the configuration control method [10.41].

In detail, let us consider the vector $\mathbf{t}_c = (t_{c,1} \dots t_{c,p})^T$ that describes the tasks to be fulfilled in addition to the M -dimensional end-effector task \mathbf{t} . In the general case $P \leq N - M$, although full redundancy exploitation suggests the consideration of exactly as many additional tasks as the number of redundant degrees of freedom, i. e., $P = N - M$.

The relation between the joint-space coordinate vector \mathbf{q} and the *constraint-task* vector \mathbf{t}_c can be considered as a direct kinematics equation

$$\mathbf{t}_c = \mathbf{k}_c(\mathbf{q}), \quad (10.35)$$

where \mathbf{k}_c is a continuous nonlinear vector function. Accordingly, it is useful to consider the mapping

$$\dot{\mathbf{t}}_c = \mathbf{J}_c(\mathbf{q}) \dot{\mathbf{q}}, \quad (10.36)$$

which can be obtained by differentiating Eq. (10.35). In (10.36), $\dot{\mathbf{t}}_c$ is the constraint-task velocity vector, and $\mathbf{J}_c(\mathbf{q}) = \partial \mathbf{k}_c / \partial \mathbf{q}$ is the $P \times N$ *constraint-task Jacobian* matrix.

At this point, an *augmented-task* vector can be defined by stacking the end-effector task vector with the constraint-task vector as

$$\mathbf{t}_a = \begin{pmatrix} \mathbf{t} \\ \mathbf{t}_c \end{pmatrix} = \begin{pmatrix} \mathbf{k}_t(\mathbf{q}) \\ \mathbf{k}_c(\mathbf{q}) \end{pmatrix}.$$

According to this definition, finding a joint configuration \mathbf{q} that results in some desired value for \mathbf{t}_a means satisfying both the end-effector and the constraint task at the same time.

A solution to this problem can be found at the differential level by inverting the mapping

$$\dot{\mathbf{t}}_a = \mathbf{J}_a(\mathbf{q}) \dot{\mathbf{q}}, \quad (10.37)$$

where the matrix

$$\mathbf{J}_a = \begin{pmatrix} \mathbf{J}_t \\ \mathbf{J}_c \end{pmatrix}$$

is referred to as the *augmented Jacobian*.

A particular choice for the constraint-task vector is $\mathbf{t}_c = \mathbf{h}(\mathbf{q})$, with \mathbf{h} defined as explained in 10.4.1, which allows the augmented Jacobian method to embed the extended Jacobian one.

10.5.3 Algorithmic Singularities

The specification of additional goals besides tracking the end-effector velocity raises the possibility that configurations exist at which the augmented kinematics problem is singular while the sole end-effector task kinematics is not; these configurations are referred to as *algorithmic singularities* [10.35]. In terms of the velocity mappings (10.33) and (10.37), an algorithmically singular configuration is one at which the extended and the augmented Jacobians, respectively, are singular while \mathbf{J}_t is full-rank.

When he introduced task-augmentation redundancy resolution methods, *Baillieul* pointed out that algorithmic singularities are not a specific problem of the extended Jacobian technique but that they arise from the way in which the constraint task conflicts with the end-effector task [10.35, 37]. This is easily understandable in the simple problem of trajectory tracking with obstacle avoidance: if the assigned trajectory passes through an obstacle either the trajectory is tracked or the obstacle is avoided so that both tasks cannot be achieved. If the origin of the conflict between the two tasks has

a clear meaning the algorithmic singularity may then be avoided by keenly specifying the constraint task case by case [10.23]. In more general situations analytical tools may be useful in finding algorithmic singularities and guiding the choice of the constraint function [10.42] or in finding configurations that better harmonize the two tasks [10.43].

In terms of the tasks definitions given by (10.2) and (10.36), one can see that the two tasks are in conflict when

$$\mathcal{R}(\mathbf{J}_c^T) \cap \mathcal{R}(\mathbf{J}_t^T) \neq \{\mathbf{0}\}, \quad (10.38)$$

which is the condition for the occurrence of an algorithmic singularity. On the other hand, when

$$\mathcal{R}(\mathbf{J}_c^T) \cap \mathcal{R}(\mathbf{J}_t^T) = \{\mathbf{0}\},$$

the two tasks are compatible because the two inverse mappings are linearly independent; a special case of task compatibility is when

$$\mathcal{R}(\mathbf{J}_c^T) \equiv \mathcal{R}^\perp(\mathbf{J}_t^T), \quad (10.39)$$

and the two mappings are orthogonal.

At the algorithmic singularities the augmented Jacobian cannot be inverted but singularity-robust techniques can be adopted. Because the exact solution does not exist there are reconstruction errors and these affect both the task vectors. To counteract this problem the use of weighted damped least-squares has been considered to invert the augmented Jacobian matrix [10.44, 45]. A different approach is the so-called task priority inverse kinematics.

10.5.4 Task Priority

Conflicts between the end-effector task and the constraint task are handled in the framework of the task-priority strategy by suitably assigning an order of priority to the given tasks and then satisfying the lower-priority task only in the null space of the higher-priority task [10.46, 47]. In the typical case, an end-effector task is considered as the primary task, although examples can occur when it becomes the secondary task [10.23]. The idea is that, when an exact solution does not exist, the reconstruction error should only affect the lower-priority task.

With reference to solution (10.12), the task-priority method consists of computing $\dot{\mathbf{q}}_0$ to suitably achieve the P -dimensional constraint-task velocity $\dot{\mathbf{i}}_c$. The projection of $\dot{\mathbf{q}}_0$ onto the null space of \mathbf{J}_t ensures that the

lower priority of the constraint task will not affect the higher priority end-effector task [10.48].

When the secondary task $\dot{\mathbf{i}}_c$ is orthogonal to the primary task $\dot{\mathbf{i}}$ (in the sense of (10.39)) the joint velocity

$$\dot{\mathbf{q}}_0 = \mathbf{J}_c^\dagger(\mathbf{q})\dot{\mathbf{i}}_c \quad (10.40)$$

would easily solve the problem, because it would already be a null-space velocity for the primary-task velocity mapping (10.2), i.e., projection through $\mathbf{N}_{\mathbf{J}_t}$ would not be needed. However, in the general case the two tasks may be compatible but not orthogonal or may conflict and there may not exist a joint velocity solution that ensures the achievement of both $\dot{\mathbf{i}}$ and $\dot{\mathbf{i}}_c$. To be consistent with the defined order of priority between the two tasks, a reasonable choice is then to guarantee exact tracking of the primary-task velocity while minimizing the constraint-task velocity reconstruction error $\dot{\mathbf{i}}_c - \mathbf{J}_c\dot{\mathbf{q}}$; this gives [10.49]

$$\dot{\mathbf{q}}_0 = \left[\mathbf{J}_c(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \right]^\dagger (\dot{\mathbf{i}}_c - \mathbf{J}_c \mathbf{J}_t^\dagger \dot{\mathbf{i}}). \quad (10.41)$$

Finally, by observing that the null-space projection operator is both hermitian and idempotent, the solution given by (10.12) and (10.41) can be simplified to [10.46]

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{i}} + \left[\mathbf{J}_c(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \right]^\dagger (\dot{\mathbf{i}}_c - \mathbf{J}_c \mathbf{J}_t^\dagger \dot{\mathbf{i}}). \quad (10.42)$$

It can be recognized that the problem of algorithmic singularities still remains; in fact, when condition (10.38) is satisfied the matrix $\mathbf{J}_c(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t)$ loses rank with full-rank \mathbf{J}_t and \mathbf{J}_c . However, in contrast to the task-space augmentation approach, correct primary-task solutions are expected as long as the sole primary-task Jacobian matrix is full-rank. Away from the algorithmic singularities the task-priority strategy gives the same solution as the task-space augmentation approach; this implies that close to an algorithmic singularity the solution becomes ill-conditioned and large joint velocities may result. This problem can be solved by using a continuous version of the truncated SVD as described in [10.3].

Another approach is to relax minimization of the secondary-task velocity reconstruction constraint and simply pursue tracking of the components of (10.40) that do not conflict with the primary task [10.50, 51], namely

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{i}} + (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \mathbf{J}_c^\dagger \dot{\mathbf{i}}_c. \quad (10.43)$$

An intuitive justification of this solution can be given as follows: The pseudoinverses \mathbf{J}_t^\dagger and \mathbf{J}_c^\dagger are used to solve separately for the joint velocities associated with the respective task velocities; the joint velocity associated with the (secondary) constraint task is then projected onto the null space of \mathbf{J}_t to remove the components that would interfere with the (primary) end-effector task and finally added to the joint velocity associated with the end-effector task. As a result, a nice property of solution (10.43) is that algorithmic singularities are decoupled from the singularities of \mathbf{J}_c .

By construction, the solution (10.43) leads to larger constraint-task reconstruction errors than solu-

tion (10.42); this is the price to be paid for smoother trajectories for the joint velocity when tracking conflicting tasks. In any case, a CLIK implementation will allow one to recover from the secondary-task tracking error due to the algorithmic singularities. In this case, the CLIK formulation becomes

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \mathbf{w}_t + (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \mathbf{J}_c^\dagger \mathbf{w}_c ,$$

with

$$\mathbf{w}_t = \dot{\mathbf{t}} + \mathbf{K}_t (\mathbf{t} - \mathbf{k}_t(\mathbf{q})) ,$$

$$\mathbf{w}_c = \dot{\mathbf{c}} + \mathbf{K}_c (\mathbf{c} - \mathbf{k}_c(\mathbf{q})) .$$

10.6 Second-Order Redundancy Resolution

Redundancy resolution at the acceleration level allows the consideration of dynamic performance along the manipulator motion. Moreover, the obtained acceleration profiles can be directly used as reference signals (together with the corresponding positions and velocities) of a task-space dynamic controller. On the other hand, a second-order redundancy resolution scheme is invariably more demanding in terms of computational load.

The simplest scheme operating at the acceleration level is represented by (10.15), i.e., the solution with the minimum norm among those that realize the task constraint (10.8). Similar to the velocity-level pseudoinverse solution, the joint movement generated by this locally optimal solution does not result in global acceleration minimization along the entire manipulator motion. Remarkably, however, the use of (10.15) does lead to the minimization of the integral index

$$\int_{t_i}^{t_f} \dot{\mathbf{q}}^T \dot{\mathbf{q}} dt ,$$

over $[t_i, t_f]$ provided that the appropriate boundary conditions are satisfied [10.52]. For example, in the case of free endpoints (neither joint positions nor velocities specified at t_i and t_f) the boundary conditions to be satisfied are split and expressed as

$$\dot{\mathbf{q}}(\bar{t}) = \mathbf{J}_t^\dagger \dot{\mathbf{t}}(\bar{t}) , \quad \bar{t} = t_i, t_f .$$

Thus, in spite of the apparent simplicity and elegance of the solution (10.15), actual minimization of the above integral requires the solution of a two-point boundary value problem (TPBVP), which is a computationally intensive numerical procedure impractical for real-time

kinematic control. However, this may be perfectly acceptable for offline redundancy resolution in an industrial setting.

More flexibility in the choice of (both local and global) performance criteria is obviously obtained by considering the full second-order solution (10.14). Let the manipulator dynamic model be expressed as

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \boldsymbol{\tau}_g(\mathbf{q}) , \quad (10.44)$$

where $\boldsymbol{\tau}$ is the vector of actuator torques, \mathbf{H} is the manipulator inertia matrix, \mathbf{c} is the vector of centrifugal/Coriolis terms, and $\boldsymbol{\tau}_g$ is the gravitational torque vector. Choosing the null-space acceleration in (10.14) as

$$\ddot{\mathbf{q}}_0 = -[\mathbf{H}(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t)]^\dagger \tilde{\boldsymbol{\tau}} , \quad (10.45)$$

with

$$\tilde{\boldsymbol{\tau}} = \mathbf{H} \mathbf{J}_t^\dagger (\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t \dot{\mathbf{q}}) + \mathbf{c} + \boldsymbol{\tau}_g$$

leads to the local minimization of the actuator torque norm $\boldsymbol{\tau}^T \boldsymbol{\tau}$ [10.53]. This particular redundancy resolution scheme performs reasonably over short tasks, but may lead to instability (more precisely, very high joint torques) in the long run, essentially due to the build-up of null-space joint velocities. Note also that the matrix product $\mathbf{H}(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t)$ in (10.45) is not full-rank; however, its pseudoinverse can be efficiently calculated using the procedure given in [10.54]. Minimization of the integral joint torque is also possible [10.55]; this solution obviously avoids the instability problem, but once again the solution of a TPBVP is required.

Another interesting inverse solution is the following

$$\ddot{\mathbf{q}} = \mathbf{J}_{t,H}^\dagger (\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t \dot{\mathbf{q}}) + (\mathbf{I} - \mathbf{J}_{t,H}^\dagger \mathbf{J}_t) \mathbf{H}^{-1} \mathbf{c}, \quad (10.46)$$

which is slightly modified with respect to the general formula (10.14) in view of the use of a weighted pseudoinverse. In particular, $\mathbf{J}_{t,H}^\dagger$ is the inertia-weighted task Jacobian pseudoinverse, given in the full-rank case by the following expression

$$\mathbf{J}_{t,H}^\dagger = \mathbf{H}^{-1} \mathbf{J}_t^T (\mathbf{J}_t \mathbf{H}^{-1} \mathbf{J}_t^T)^{-1}.$$

10.7 Cyclicity

A common drawback of redundancy resolution schemes based on differential kinematics is the lack of *cyclicity* (also called *repeatability*): in general, the joint-space trajectory corresponding to a cyclic task space trajectory is not cyclic itself (i. e., the final position of the joints does not coincide with the initial position). This phenomenon is clearly undesirable, because it basically means that the behavior of the manipulator along periodic tasks to be repeated over and over is unpredictable.

A mathematical condition for cyclicity exists for a particular class of redundancy resolution methods [10.56]. In particular, consider any scheme of the form

$$\dot{\mathbf{q}} = \mathbf{G}_t(\mathbf{q}) \dot{\mathbf{t}}, \quad (10.47)$$

where \mathbf{G}_t is any *generalized inverse* of the task Jacobian \mathbf{J}_t , i. e., an $N \times M$ matrix such that $\mathbf{J}_t \mathbf{G}_t \mathbf{J}_t = \mathbf{J}_t$ (the pseudoinverse matrix \mathbf{J}_t^\dagger in (10.13) is a particular generalized inverse). Assume that the assigned task $\mathbf{t}(t)$ describes a cyclic trajectory in a simply connected region of the task space, and denote by $\mathbf{g}_i(\mathbf{q})$ the i -th column of \mathbf{G}_t . A necessary and sufficient condition for (10.47) to generate cyclic joint trajectories is that

The solution (10.46) minimizes

$$\int_{t_i}^{t_f} \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{H}(\mathbf{q}) \dot{\mathbf{q}} dt,$$

i. e., the integral over $[t_i, t_f]$ of the manipulator kinetic energy [10.52]. Once again, the correct boundary conditions must be used; for example, the case of free endpoints leads to

$$\dot{\mathbf{q}}(\bar{t}) = \mathbf{J}_{t,H}^\dagger \dot{\mathbf{t}}(\bar{t}), \quad \bar{t} = t_i, t_f.$$

the *distribution*

$$\Delta_{\mathbf{G}_t}(\mathbf{q}) = \text{span}\{\mathbf{g}_{t1}(\mathbf{q}), \dots, \mathbf{g}_{tM}(\mathbf{q})\}$$

is involutive (i. e., it is closed under the Lie bracket operation).

It should be emphasized that the involutivity of $\Delta_{\mathbf{G}_t}$ is a strong condition, because it must be satisfied at any configuration. This suggests that most generalized inverses are not cyclic. Note also that the above condition for cyclicity depends on the chosen generalized inverse (i. e., pseudoinverse, weighted pseudoinverse, and so on) as well as on the form of \mathbf{J}_t , which in turn is related to the mechanical structure of the manipulator. This means that cyclicity must be established on a case-by-case basis. However, it is possible to design a repeatable inverse that can approximate any desired generalized inverse over a specified subset of the workspace [10.57].

As for redundancy resolution schemes which do not fall in the class (10.47) – namely, those entailed by the general inverse solution (10.12) – they are in general not cyclic. In particular, this is true for when local optimization is used to solve redundancy, as in (10.31). A notable exception is the extended Jacobian method, which is always cyclic.

10.8 Fault Tolerance

One natural use for kinematic redundancy is that of fault tolerance, i. e., if there are more degrees of freedom than the minimum required to complete a task then one should, theoretically, be able to tolerate a joint failure and still complete the desired task. While component failures for robots employed in structured and benign environments where regular maintenance can be performed are relatively rare, there are many important

applications, although less common, where this is not true, e.g., in space or underwater exploration and in nuclear environments. The failure rates for components in such harsh environments are relatively high [10.58] and maintenance is not possible. Many of these component failures will result in a robot's joint becoming immobilized, i. e., a locked joint failure mode [10.59]. Component failures that result in other common fail-

ure modes, e.g., free-swinging joint failures [10.60], are also frequently transformed into the locked joint failure mode by failure recovery mechanisms that employ fail safe brakes [10.61].

A large body of work on fault-tolerant manipulators has focused on the kinematic properties of redundant robots, both of serial and parallel structure [10.62]. These analyses have been performed both on the local properties associated with the manipulator Jacobian [10.63, 64] as well as the global characteristics such as the resulting workspace following a particular failure [10.65–67]. Clearly both local and global kinematic properties are related, e.g., if a robot is at a workspace boundary then the Jacobian is singular.

The effect of locked joint failures on the motion capabilities of a robotic manipulator are most easily characterized when the manipulator Jacobian is represented as a collection of columns

$$\mathbf{J}_{M \times N} = (\mathbf{J}_1 \quad \mathbf{J}_2 \quad \dots \quad \mathbf{J}_N),$$

where \mathbf{J}_i represents the end-effector velocity due to the velocity of joint i . For an arbitrary single joint failure at joint f , assuming that the failed joint can be locked, the resulting $(M \times (N-1))$ Jacobian will be missing the f -th column, where f can range from 1 to N . This Jacobian will be denoted by a preceding superscript so that in general

$${}^f\mathbf{J}_{M \times (N-1)} = (\mathbf{J}_1 \quad \mathbf{J}_2 \quad \dots \quad \mathbf{J}_{f-1} \quad \mathbf{J}_{f+1} \quad \dots \quad \mathbf{J}_N).$$

As noted above, the local velocity properties of a manipulator Jacobian are frequently quantified in terms of the singular values. Most local dexterity measures can be defined in terms of simple combinations of these singular values such as their product (determinant), sum (trace), or ratio (condition number). The most significant of the singular values is σ_M , the minimum singular value, because it is by definition the measure of proximity to a singularity and tends to dominate the behavior of both the manipulability (determinant) and the condition number. The minimum singular value is also a measure of the worst-case dexterity over all possible end-effector motions. One definition of failure tolerance is based on the worst-case dexterity following an arbitrary locked joint failure. Because ${}^f\sigma_M$ denotes the minimum singular value of ${}^f\mathbf{J}$, it is a measure of the worst-case dexterity if joint f fails. If all joints are equally likely to fail, then a measure of the worst-case failure tolerance is given by

$$K = \min_{f=1}^N {}^f\sigma_M.$$

Physically, this amounts to minimizing the worst-case increase in joint velocity when a joint is locked and

the others must accelerate to maintain the desired end effector trajectory. In addition, maximizing K is equivalent to locally maximizing the distance to a post-failure workspace boundary [10.68]. To insure that manipulator performance is optimal prior to a failure, one may want to further define an optimally failure tolerant Jacobian as having all equal singular values due to the desirable properties of isotropic manipulator configurations. Under these conditions, to guarantee that the minimum ${}^f\sigma_M$ is as large as possible they should all be equal. It is easy to show that the worst-case dexterity of an isotropic manipulator that experiences a single joint failure is governed by the inequality

$$K = \min_{f=1}^N {}^f\sigma_M \leq \sigma \sqrt{\frac{(N-M)}{N}},$$

where σ denotes the norm of the original Jacobian. The best case of equality occurs if the manipulator is in an optimally failure tolerant configuration. The above inequality makes sense from a physical point of view because it represents the ratio of the degree of redundancy to the original number of degrees of freedom. Using the above definition of an optimally failure tolerant configuration one can identify the structure of the Jacobian required to obtain this property [10.63]. In particular, one can show that the optimally failure tolerant criteria requires that each joint contributes equally to the null space of the Jacobian transformation. Physically, this means that the redundancy of the robot is uniformly distributed among all the joints so that a fail-

Fig. 10.9 A four degree-of-freedom spatial positioning manipulator in a configuration that is optimally fault tolerant

ure at any one joint can be compensated for by the remaining joints.

A simple example of an optimally failure tolerant configuration that is easy to visualize is that of a spatial positioning manipulator with four joints whose Jacobian is given by

$$\mathbf{J}_v = \begin{pmatrix} -\sqrt{3/4} & \sqrt{1/12} & \sqrt{1/12} & \sqrt{1/12} \\ 0 & -\sqrt{2/3} & \sqrt{1/6} & \sqrt{1/6} \\ 0 & 0 & -\sqrt{1/2} & \sqrt{1/2} \end{pmatrix},$$

where \mathbf{J}_v represents the linear velocity portion of a manipulator Jacobian. The null space at this configuration is given by $(1/2)[1 \ 1 \ 1 \ 1]^T$, which illustrates that

each joint contributes equally to the null space motion, thus distributing the redundancy proportionally to all degrees of freedom. If the four possible single locked joint failures are considered, one can show that

$$\begin{aligned} {}^f\sigma_3 &= K_{\max} = \frac{1}{2}, \\ f &= 1, \dots, 4, \end{aligned}$$

which satisfies the optimally failure tolerant criterion. It is then possible to design physical robot manipulators that possess this Jacobian along with its associated optimal kinematic properties. An example of one such robot is shown in Fig. 10.9 [10.69].

10.9 Conclusion and Further Reading

Research on kinematically redundant robots has been flourishing for over two decades now, and is still very active. The number of papers dealing with this subject is therefore enormous. The few works cited below are simply a small addition to the fundamental contributions already referenced so far, and constitute by no means an exhaustive list.

The mechanical design of kinematically redundant manipulators has been studied in many papers [10.70–74]. In particular, the superiority of human-arm-like manipulators over conventional 6-DOF robots was first advocated in [10.75]. Reconfiguration of this arm so as to ensure full mobility in the whole workspace is studied in [10.76, 77].

A general analysis of the inverse kinematic problem for redundant manipulators is presented in [10.78]. In particular, the geometric structure of self-motions is analyzed in [10.79].

Weighting the damped least-squares solution for guaranteed singularity avoidance in anisotropic end-effector tasks was proposed in [10.9, 21, 80].

In addition to singularity avoidance, redundancy has also been exploited to achieve obstacle avoid-

ance [10.37, 46, 81, 82], minimization of the effects of joint elasticity [10.83], fault tolerance [10.60], reduction of impact force [10.84, 85], and maximization of various dexterity measures [10.4, 5, 43, 86]. A completely different approach for obstacle avoidance with redundant robots is presented in [10.87].

A review of redundancy resolution via local optimization is given in [10.88]. A numerically efficient alternative for redundancy resolution via local optimization is proposed in [10.89]. A redundancy resolution approach with somehow intermediate characteristics between local and global optimization is presented in [10.90]. Other methods for second-order redundancy resolution are discussed, e.g., in [10.91]. Also worth citing is the dynamically consistent generalized inverse of [10.92].

The cyclicity issue was first pointed out in [10.93], and further investigated, e.g., in [10.94, 95]. General formalisms for redundancy resolution of vehicle-manipulator systems subject to nonholonomic constraints are described in [10.96, 97].

11. Robots with Flexible Elements

Alessandro De Luca, Wayne J. Book

Design issues, dynamic modeling, trajectory planning, and feedback control problems are presented for robot manipulators having components with mechanical flexibility, either concentrated at the joints or distributed along the links. The chapter is divided accordingly into two main parts. Similarities or differences between the two types of flexibility are pointed out wherever appropriate.

For robots with flexible joints, the dynamic model is derived in detail by following a Lagrangian approach and possible simplified versions are discussed. The problem of computing the nominal torques that produce a desired robot motion is then solved. Regulation and trajectory tracking tasks are addressed by means of linear and nonlinear feedback control designs.

For robots with flexible links, relevant factors that lead to the consideration of distributed flexibility are analyzed. Dynamic models are presented, based on the treatment of flexibility through lumped elements, transfer matrices, or assumed modes. Several specific issues are then highlighted, including the selection of sensors, the model order

used for control design, and the generation of effective commands that reduce or eliminate residual vibrations in rest-to-rest maneuvers. Feedback control alternatives are finally discussed.

In each of the two parts of this chapter, a section is devoted to the illustration of the original references and to further readings on the subject.

The standard assumption underlying robot kinematics, dynamics, and control design is that manipulators consist only of rigid bodies (links and motion transmission components). This is, however, an ideal situation that may be considered valid only for slow motion and small interacting forces. In practice, mechanical flexibility in robot manipulators is present for two main reasons: the use of compliant transmission elements and the reduction of the mass of the moving links through the use of lightweight material and slender design. These two kinds of flexibility introduce static and dynamic deflections between the position of the driving actuators and the position of the manipulator end-effector. If flexibil-

ity is not taken into account when considering robot design and control, a degradation of the overall expected performance of the robot typically occurs.

From a modeling point of view, flexibility can be assumed as concentrated at the robot joints or distributed (in different ways) along the robot links. The dynamic modeling steps are similar, with the need to introduce additional generalized coordinates besides those used to describe the rigid motion of the robot arm. However, the properties of the resulting models are quite different from a control point of view. Therefore, the case of *robots with flexible joints* and of *robots with flexible links* are presented in this chapter mostly as

separate items, pointing out similarities or structural differences wherever appropriate. For both classes of flexible robots, the relevant design issues, dynamic modeling, inverse dynamics algorithms, and control laws for set-point regulation and trajectory tracking will be discussed. Indeed, joint and link flexibilities may

be present (and dynamically interact) at the same time. Many of the presented results can be extended to this case as well.

In the following, it is assumed that the reader is already familiar with basic issues on kinematics, dynamics, and control of rigid robots (Chaps. 2, 3, 8).

11.1 Robots with Flexible Joints

The presence of joint flexibility is common in current industrial robots, when motion transmission/reduction elements such as belts – (as in the selective compliant assembly robot arm (SCARA) family), long shafts (as in the forearm of the Unimation Puma arm), cables, harmonic drives, or cycloidal gears are used. The purpose of these components is to allow relocation of the actuators next to the robot base, thus improving dynamic efficiency, or to guarantee high reduction ratios with power-efficient compact inline devices.

However, when subject to the forces/torques arising in normal robot operation, these components are intrinsically flexible (e.g., the flexspline in harmonic drives; Fig. 11.1) and introduce a time-varying displacement between the position of the actuators and that of the driven links. Without a specific control action, an oscillatory behavior, typically of small magnitude but at a relatively high frequency, is observed at the robot end-effector level during free motion. Moreover, some form of instability (e.g., chattering) may occur in tasks involving contact with the environment.

Recently, flexible actuation/transmission elements have been deliberately selected in soft robots (such as those driven by serial elastic actuation (SEA) or variable stiffness actuation (VSA), Chap. 21) intended for physical human–robot interaction and for achieving more natural motion characteristics. In fact, this form of mechanical compliance guarantees an iner-

tial decoupling between the actuator and the (possibly, lightweight) link, thus reducing the kinetic energy involved in undesired collisions with humans. Such a safety-oriented mechanical design should be traded-off with a more complex control design aimed at preserving the same performance of rigid robots in terms of speed and accuracy of the end-effector motion (Chap. 69).

Figures 11.2 and 11.3 show two examples of robot manipulators with flexible joints, the 8R robot *Dex-*

Fig. 11.1 The components of a harmonic drive

Fig. 11.2 The cable-driven robot *Dexter* by Scienza Machinale

ter and the 7R lightweight manipulator *DLR LWR-III*. The first robot has motors 3–8 located inside the second link, with motion transmitted to the distal links through steel cables and pulleys; the second robot has a modular structure, with each motor integrated in the associated joint and using an harmonic drive as reduction element. The joint stiffnesses of the *Dexter* robot vary between 120 and 6300 N m/rad depending on the joint, while for the *DLR LWR-III* manipulator, the range is 6000–15 000 N m/rad. These numerical values refer to deflections and associated torques evaluated after the reduction gears.

Deflection of the flexible transmission elements can be modeled as being *concentrated at the joints* of the robot, thus limiting the complexity of the associated equations of motion. When compared to the rigid case, the dynamic model of robots with flexible joints (and rigid links) requires *twice* the number of generalized coordinates to completely characterize the configuration of all rigid bodies (motors and links) constituting the arm.

As a result, the case of flexible joint robots is one example in which the number of control inputs is strictly less than the number of mechanical degrees of freedom. This suggests that the design of control schemes re-

alizing standard motion tasks is expected to be more difficult than for rigid robots. Moreover, the implementation of a full state feedback law will require twice the number of sensors, measuring quantities that are *before* and *after* (or across) the joint deformation. On the other hand, the motor torques used to command the robot as well as the disturbance torques due to joint flexibility perform work on the same joint axes (they are *physically collocated*). It should be noted that this is one relevant difference with respect to the case of flexibility distributed along the links. This characteristic is very helpful for rejecting vibrations and controlling the overall robot motion. Roughly speaking, we will be able to use input commands acting before the source of flexibility to ensure that output variables defined beyond the flexibility behave in a desired way.

11.1.1 Dynamic Modeling

Dynamic models that explicitly include joint flexibility are used to evaluate quantitatively vibratory effects superposed on the rigid motion, verify whether the control laws obtained under the assumption of joint rigidity can still work in practice (or to what extent they should be modified), and enable the design of new model-based feedforward and feedback controllers.

We consider a robot with flexible joints as an open kinematic chain having $N + 1$ rigid bodies, the base and the N links, interconnected by N (rotary or prismatic) joints undergoing deflection, and actuated by N electrical drives. From a mechanical point of view, each motor (with its stator and rotor) is an additional rigid body with its inertial properties. All joints are considered to be flexible, though mixed situations may be encountered due to the use of different transmission devices. When reduction gearings are present, they are modeled as being placed *before* the joint deflection occurs.

The following standard assumptions are made:

- A1** Joint deflections are small, so that flexibility effects are limited to the domain of linear elasticity.
- A2** The actuators' rotors are modeled as uniform bodies having their center of mass on the rotation axis.
- A3** Each motor is located on the robot arm in a position preceding the driven link. (This can be generalized to the case of multiple motors simultaneously driving multiple distal links.)

The first assumption supports the terminology of robots with *elastic* joints often used in the literature. The elasticity at joint i is modeled by a spring of stiff-

Fig. 11.3 The lightweight manipulator *DLR LWR-III* by the German Aerospace Center

ness $K_i > 0$, which is torsional for rotational joints and linear for translational ones. Figure 11.4 shows a single link driven by a motor through a rotational elastic joint. Nonlinear stiffness characteristics for the flexible joint can also be considered, provided that the map from deflection to force is smooth and invertible. Assumption A2 is a basic requirement for the long life of an electrical drive, and thus very reasonable. As we will see, it implies that the inertia matrix and the gravity term in the robot dynamic model will be independent of the angular position of the motors. A typical arrangement of motors satisfying assumption A3 is shown in Fig. 11.5. The simplest situation is when the i -th motor moves link i and is mounted on link $i - 1$ with its rotation axis aligned with the i -th joint. This is, for instance, the case for the *LWR-III* manipulator. The dislocation of the actuating motors along the structure has a great influence on the structure of the dynamic equations of motion.

For kinematic and dynamic analysis, $2N$ frames are attached to the $2N$ moving rigid bodies (links and motors) in the robot chain: the link frames L_i and the motor frames R_i , for $i = 1, \dots, N$ (Fig. 11.5). For the definition of the link frames L_i , the standard Denavit–Hartenberg convention can be used. The frames R_i are attached to the motor stators, aligned with the axes of

Fig. 11.4 Schematic representation of an elastic joint

Fig. 11.5 Arrangement of motors and links in an open kinematic chain

symmetry of the motors and with the z -axis along the spinning direction of the rotor.

Accordingly, $2N$ generalized coordinates will be needed. A possible set of coordinates is given by

$$\Theta = \begin{pmatrix} \mathbf{q} \\ \boldsymbol{\theta} \end{pmatrix} \in \mathbb{R}^{2N},$$

where \mathbf{q} is the N -vector of link positions and $\boldsymbol{\theta}$ is the N -vector of motor (i.e., rotor) positions, as reflected through the transmission/reduction gears. This choice of variables is quite convenient because:

1. The model will be formally independent of the reduction ratios.
2. These position variables will have a similar dynamic range.
3. The kinematics of the robot will be a function of the link variables \mathbf{q} only (these variables are already *beyond* the joint flexibility) so that all issues related to direct/inverse kinematics will be identical to the case of fully rigid robots.

For some considerations, it is also useful to define the variable $\boldsymbol{\theta}_m$, namely the N -vector of motor positions before reduction, which are the quantities directly measured by encoders mounted on the motors. In the case of a motor directly placed on the i -th joint axis, one has $\dot{\theta}_{m,i} = n_i \dot{\theta}_i$, where $n_i \geq 1$ is the reduction ratio at the i -th joint. In addition, for $i = 1, \dots, N$, the difference

$$\delta_i = q_i - \theta_i$$

is the deflection at the i -th joint, while

$$\tau_{J,i} = K_i(\theta_i - q_i)$$

is the torque transmitted to the i -th link through the associated elastic spring (Fig. 11.4) – the quantity measured by a joint torque sensor, whenever present. Note that for robots with flexible links, the set $(\boldsymbol{\theta}, \boldsymbol{\delta})$ is typically used in the dynamic modeling, where $\boldsymbol{\delta}$ is the vector of link deflection coordinates.

Following a Lagrangian approach, the single energy contributions to the Lagrangian

$$\mathcal{L} = \mathcal{T}(\boldsymbol{\Theta}, \dot{\boldsymbol{\Theta}}) - \mathcal{U}(\boldsymbol{\Theta})$$

will be derived next.

The *potential energy* of the robot is due to gravity and joint elasticity. The gravity part is related to the position of the barycenter of the links (each of mass m_i) and of the motors (of mass m_{r_i}). Because of assumption A2, the latter will be independent of $\boldsymbol{\theta}$. Thus,

$$\mathcal{U}_{\text{grav}} = \mathcal{U}_{\text{grav,link}}(\mathbf{q}) + \mathcal{U}_{\text{grav,motor}}(\mathbf{q}).$$

For the elastic part of the potential, because of assumption **A1**, we have

$$\mathcal{U}_{\text{elas}} = \frac{1}{2} (\mathbf{q} - \boldsymbol{\theta})^T \mathbf{K} (\mathbf{q} - \boldsymbol{\theta}),$$

$$\mathbf{K} = \text{diag}(K_1, \dots, K_N).$$

As a result,

$$\mathcal{U}(\boldsymbol{\Theta}) = \mathcal{U}_{\text{grav}}(\mathbf{q}) + \mathcal{U}_{\text{elas}}(\mathbf{q} - \boldsymbol{\theta}).$$

The *kinetic energy* of the robot is the sum of the link and rotor contributions. For the links, there is no difference with respect to the standard rigid robot case and it will be sufficient to write in general

$$\mathcal{T}_{\text{link}} = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_L(\mathbf{q}) \dot{\mathbf{q}}, \quad (11.1)$$

with the positive-definite symmetric link inertia matrix $\mathbf{M}_L(\mathbf{q})$. For the rotors, some more details are needed

$$\begin{aligned} \mathcal{T}_{\text{rotor}} &= \sum_{i=1}^N \mathcal{T}_{\text{rotor}_i} \\ &= \sum_{i=1}^N \left(\frac{1}{2} m_{r_i} \mathbf{v}_{r_i}^T \mathbf{v}_{r_i} + \frac{1}{2} {}^{R_i} \boldsymbol{\omega}_{r_i}^T {}^{R_i} \mathbf{I}_{r_i} {}^{R_i} \boldsymbol{\omega}_{r_i} \right), \end{aligned} \quad (11.2)$$

where \mathbf{v}_{r_i} is the linear velocity of the center of mass of the i -th rotor and $\boldsymbol{\omega}_{r_i}$ is the angular velocity of the i -th rotor body. All quantities in the angular contributions in (11.2) are conveniently expressed in the local frame R_i . According to assumption **A2**, the rotor inertia matrix is then diagonal

$${}^{R_i} \mathbf{I}_{r_i} = \text{diag}(I_{r_{ixx}}, I_{r_{iyy}}, I_{r_{izz}}),$$

with $I_{r_{ixx}} = I_{r_{iyy}}$, while \mathbf{v}_{r_i} can be expressed as a function of \mathbf{q} and $\dot{\mathbf{q}}$ only. Moreover, due to assumption **A3**, the angular velocity of the i -th rotor has the general expression

$${}^{R_i} \boldsymbol{\omega}_{r_i} = \sum_{j=1}^{i-1} \mathbf{J}_{r_{i,j}}(\mathbf{q}) \dot{q}_j + \begin{pmatrix} 0 \\ 0 \\ \dot{\theta}_{m,i} \end{pmatrix}, \quad (11.3)$$

where $\mathbf{J}_{r_{i,j}}(\mathbf{q})$ is the j -th column of the Jacobian relating the link velocities $\dot{\mathbf{q}}$ to the angular velocity of the i -th rotor in the robot chain. By substituting (11.3) into (11.2) and expressing $\dot{\theta}_m$ in terms of $\dot{\boldsymbol{\theta}}$, it can be shown that

$$\begin{aligned} \mathcal{T}_{\text{rotor}} &= \frac{1}{2} \dot{\mathbf{q}}^T [\mathbf{M}_R(\mathbf{q}) + \mathbf{S}(\mathbf{q}) \mathbf{B}^{-1} \mathbf{S}^T(\mathbf{q})] \dot{\mathbf{q}} \\ &\quad + \dot{\mathbf{q}}^T \mathbf{S}(\mathbf{q}) \dot{\boldsymbol{\theta}} + \frac{1}{2} \dot{\boldsymbol{\theta}}^T \mathbf{B} \dot{\boldsymbol{\theta}}, \end{aligned} \quad (11.4)$$

where \mathbf{B} is the constant diagonal inertia matrix collecting the rotors inertial components $I_{r_{izz}}$ around their spinning axes, as reflected through the reduction ratios, $\mathbf{M}_R(\mathbf{q})$ contains the rotor masses (and, possibly, the rotor inertial components along the other principal axes), and the square matrix $\mathbf{S}(\mathbf{q})$ expresses the inertial couplings between the rotors and the previous links in the robot chain.

A simple example illustrates the derivation and the actual expressions of the terms in (11.4). We also include the reduction elements to show how the rotor inertial component around the spinning axis will appear in the kinetic energy, weighted by different powers of the reduction ratios. Consider a planar robot with two rotational elastic joints, a first link of length ℓ_1 , and motors mounted directly on the joint axes. The kinetic energies of the two rotors are

$$\begin{aligned} \mathcal{T}_{\text{rotor}_1} &= \frac{1}{2} I_{r_{1zz}} \dot{\theta}_{m,1}^2 = \frac{1}{2} I_{r_{1zz}} n_1^2 \dot{\theta}_1^2 \\ \mathcal{T}_{\text{rotor}_2} &= \frac{1}{2} m_{r_2} \ell_1^2 \dot{q}_1^2 + \frac{1}{2} I_{r_{2zz}} (\dot{q}_1 + \dot{\theta}_{m,2})^2 \\ &= \frac{1}{2} m_{r_2} \ell_1^2 \dot{q}_1^2 + \frac{1}{2} I_{r_{2zz}} (\dot{q}_1^2 + 2n_2 \dot{q}_1 \dot{\theta}_2 + n_2^2 \dot{\theta}_2^2), \end{aligned}$$

leading to

$$\begin{aligned} \mathbf{B} &= \begin{pmatrix} I_{r_{1zz}} n_1^2 & 0 \\ 0 & I_{r_{2zz}} n_2^2 \end{pmatrix}, \quad \mathbf{S} = \begin{pmatrix} 0 & I_{r_{2zz}} n_2 \\ 0 & 0 \end{pmatrix}, \\ \mathbf{M}_R &= \begin{pmatrix} m_{r_2} \ell_1^2 & 0 \\ 0 & 0 \end{pmatrix}, \quad \mathbf{S} \mathbf{B}^{-1} \mathbf{S}^T = \begin{pmatrix} I_{r_{2zz}} & 0 \\ 0 & 0 \end{pmatrix}. \end{aligned}$$

In this specific case, the matrix \mathbf{S} (as well as \mathbf{M}_R) is constant. Note that for large reduction ratios n_i , the dominant inertial effect due to the rotors is given by the matrix \mathbf{B} . Also, if the second motor was mounted remotely on the first joint (as it is often the case in the class of SCARA arms), or still close to the second joint but with the spinning axis orthogonal to the axis of this joint, then the matrix \mathbf{S} would be zero.

In general, as a consequence of assumption **A3**, the matrix $\mathbf{S}(\mathbf{q})$ has always a strictly upper triangular structure with a cascaded dependence of its nonzero elements

$$\mathbf{S}(\mathbf{q}) = \begin{pmatrix} 0 & S_{12} & S_{13}(q_2) & S_{14}(q_2, q_3) & \dots & \dots & S_{1N}(q_2, \dots, q_{N-1}) \\ 0 & 0 & S_{23} & S_{24}(q_3) & \dots & \dots & S_{2N}(q_3, \dots, q_{N-1}) \\ 0 & 0 & 0 & S_{34} & \dots & \dots & S_{3N}(q_4, \dots, q_{N-1}) \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 0 & S_{N-2,N-1} & S_{N-2,N}(q_{N-1}) \\ 0 & 0 & 0 & \dots & 0 & 0 & S_{N-1,N} \\ 0 & 0 & 0 & \dots & 0 & 0 & 0 \end{pmatrix}. \quad (11.5)$$

Summing up, the total kinetic energy of the robot is

$$\begin{aligned}\mathcal{T} &= \frac{1}{2} \dot{\Theta}^T \mathcal{M}(\Theta) \dot{\Theta} \\ &= \frac{1}{2} \begin{pmatrix} \dot{q}^T & \dot{\theta}^T \end{pmatrix} \begin{pmatrix} \mathbf{M}(q) & \mathbf{S}(q) \\ \mathbf{S}^T(q) & \mathbf{B} \end{pmatrix} \begin{pmatrix} \dot{q} \\ \dot{\theta} \end{pmatrix},\end{aligned}$$

with

$$\mathbf{M}(q) = \mathbf{M}_L(q) + \mathbf{M}_R(q) + \mathbf{S}(q)\mathbf{B}^{-1}\mathbf{S}^T(q). \quad (11.6)$$

As anticipated, the total inertia matrix \mathcal{M} of the robot depends only on q .

Using the Lagrange equations, finally yields the complete dynamic model

$$\begin{aligned}\begin{pmatrix} \mathbf{M}(q) & \mathbf{S}(q) \\ \mathbf{S}^T(q) & \mathbf{B} \end{pmatrix} \begin{pmatrix} \ddot{q} \\ \ddot{\theta} \end{pmatrix} + \begin{pmatrix} c(q, \dot{q}) + c_1(q, \dot{q}, \dot{\theta}) \\ c_2(q, \dot{q}) \end{pmatrix} \\ + \begin{pmatrix} g(q) + \mathbf{K}(q - \theta) \\ \mathbf{K}(\theta - q) \end{pmatrix} = \begin{pmatrix} 0 \\ \tau \end{pmatrix},\end{aligned} \quad (11.7)$$

where the inertial terms (related to the total inertia matrix $\mathcal{M}(q)$), the Coriolis and centrifugal terms (collectively denoted by $c_{\text{tot}}(\Theta, \dot{\Theta})$), and the potential terms $(\partial \mathcal{U}(\Theta)/\partial \Theta)^T$ have been written separately. In particular, $g(q) = (\partial \mathcal{U}_{\text{grav}}(q)/\partial q)^T$ while $\tau_J = \mathbf{K}(\theta - q)$ is the elastic torque transmitted through the joints.

The first N and the last N equations of the dynamic model (11.7) are referred to as the *link* and the *motor equations*, respectively.

On the right-hand side of (11.7), all nonconservative generalized forces should appear. When dissipative effects are not considered, only the motor torque τ producing work on the θ variable is present (i.e., the torques on the motor output shafts, amplified by the reduction ratios) in the motor equations. If the robot end-effector is in contact with the environment, the zero on the right-hand side of the link equations should be replaced by $\tau_{\text{ext}} = \mathbf{J}^T(q)\mathbf{F}$, where $\mathbf{J}(q)$ is the robot Jacobian and \mathbf{F} the forces/torques acting from the environment on the robot.

In the presence of energy-dissipating effects, additional terms appear on the right-hand side of (11.7). For instance, viscous friction at both sides of the transmissions and spring damping of the (visco)elastic joints give rise to the vector term

$$\begin{pmatrix} -\mathbf{F}_q \dot{q} - \mathbf{D}(\dot{q} - \dot{\theta}) \\ -\mathbf{F}_\theta \dot{\theta} - \mathbf{D}(\dot{\theta} - \dot{q}) \end{pmatrix}, \quad (11.8)$$

where the diagonal, positive-definite matrices \mathbf{F}_q , \mathbf{F}_θ , and \mathbf{D} contain, respectively, the viscous coefficients on

the link side and on the motor side, and the damping of the elastic springs at the joints. More general forms of nonlinear friction τ_F can be considered. Note that, in principle, friction acting on the motor side can be fully compensated by a suitable choice of the control torque τ , while this is not true for friction acting on the link side, due to the noncollocation.

Model Properties

All elements in the $2N$ -vector $c_{\text{tot}}(\Theta, \dot{\Theta})$ of velocity-dependent terms in (11.7) are independent of the motor position θ . The specific dependence of the N -vectors c , c_1 , and c_2 follows from the general expression of the components of c_{tot} based on Christoffel symbols

$$c_{\text{tot},i}(\Theta, \dot{\Theta}) = \frac{1}{2} \dot{\Theta}^T \left[\frac{\partial \mathcal{M}_i}{\partial \Theta} + \left(\frac{\partial \mathcal{M}_i}{\partial \Theta} \right)^T - \frac{\partial \mathcal{M}}{\partial \Theta_i} \right] \dot{\Theta},$$

for $i = 1, \dots, 2N$, where \mathcal{M}_i is the i -th column of the total inertia matrix $\mathcal{M}(\Theta)$. In particular, the velocity vectors c_1 and c_2 arise only in the presence of a configuration-dependent $\mathbf{S}(q)$ matrix. Performing calculations, it can be shown that:

1. The vector c_1 does not contain quadratic velocity terms in \dot{q} or $\dot{\theta}$, but only mixed quadratic terms $\dot{\theta}_i \dot{q}_j$.
2. When the matrix \mathbf{S} is constant (in particular, zero), both c_1 and c_2 vanish.

The dynamic model (11.7) also shares some properties of the rigid case, such as:

- The model equations admit a linear parametrization in terms of a suitable set of dynamic coefficients, including joint stiffnesses and motor inertias, which is useful for model identification and adaptive control.
- The Coriolis and centrifugal terms can always be factorized as $c_{\text{tot}}(\Theta, \dot{\Theta}) = \mathcal{C}(\Theta, \dot{\Theta})\dot{\Theta}$, in such a way that matrix $\mathcal{M} - 2\mathcal{C}$ is skew-symmetric – a property used in control analysis.
- For robots having only rotational joints, the gradient of the gravity vector $g(q)$ is globally bounded in norm by a constant.

Finally, when the joint stiffness is extremely large ($\mathbf{K} \rightarrow \infty$), then $\theta \rightarrow q$ while $\tau_J \rightarrow \tau$. It is easy to check that the dynamic model (11.7) collapses in the limit into the standard model of fully rigid robots (including links and motors).

Reduced Model

In general, the link and motor equations in (11.7) are dynamically coupled through the elastic torque τ_J at the joints, but also (at the acceleration level) via the inertial components of matrix $\mathbf{S}(q)$ – usually a path of low energy transfer. The presence and actual relevance

of these inertial couplings depend on the kinematic arrangement of the manipulator and, in particular, on the specific placement of the motors and transmission devices. There are cases in which the matrix \mathbf{S} is constant (e.g., the planar case, as in the previous example, with any number of links) or zero (e.g., for a single link with elastic joint or for a robot with $N = 2$ links having the two joint axes orthogonal and the motors mounted at the joints). As a result, the dynamic equations will simplify considerably.

For a generic robot with elastic joints, one can take advantage of the presence of large reduction ratios (with the n_i 's of the order of 100–150) and simply neglect energy contributions due to the inertial couplings between the motors and the links (see again the 2R planar example). This is equivalent to considering the following simplifying assumption:

A4 The angular velocity of the rotors is due only to their own spinning, i. e.,

$${}^{R_i}\boldsymbol{\omega}_{r_i} = \begin{pmatrix} 0 & 0 & \dot{\theta}_{m,i} \end{pmatrix}^T, \quad i = 1, \dots, N,$$

instead of the complete expression (11.3).

As a result, the total angular kinetic energy of the rotors is just $\frac{1}{2} \dot{\boldsymbol{\theta}}^T \mathbf{B} \dot{\boldsymbol{\theta}}$ (or $\mathbf{S} \equiv \mathbf{0}$), and the dynamic model (11.7) reduces to

$$\begin{aligned} \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) + \mathbf{K}(\mathbf{q} - \boldsymbol{\theta}) &= \mathbf{0} \\ \mathbf{B}\ddot{\boldsymbol{\theta}} + \mathbf{K}(\boldsymbol{\theta} - \mathbf{q}) &= \boldsymbol{\tau}, \end{aligned} \quad (11.9)$$

with $\mathbf{M}(\mathbf{q}) = \mathbf{M}_L(\mathbf{q}) + \mathbf{M}_R(\mathbf{q})$. The main feature of this model is that the link and motor equations are dynamically coupled only through the elastic torque $\boldsymbol{\tau}_J$. In addition, the motor equations are now fully linear.

We note that the complete model (11.7) and the reduced model (11.9) display different characteristics with respect to certain control problems. In fact, the reduced model is always feedback linearizable by *static* state feedback, whereas this is never the case for the complete model as soon as a coupling $\mathbf{S} \neq \mathbf{0}$ is present.

Singular Perturbation Model

It is interesting to show the *two-time-scale* dynamic behavior that it is induced in robots with elastic joints when the joint stiffness \mathbf{K} is relatively large, but still finite. This behavior can be made explicit by a simple linear change of coordinates, namely replacing $\boldsymbol{\theta}$ with the joint torque $\boldsymbol{\tau}_J$. For the sake of simplicity, this is illustrated on the reduced model only (without dissipation).

Since the diagonal joint stiffness matrix is assumed to have large but similar elements, a common scalar fac-

tor $1/\epsilon^2 \gg 1$ can be extracted as

$$\mathbf{K} = \frac{1}{\epsilon^2} \hat{\mathbf{K}} = \frac{1}{\epsilon^2} \text{diag}(\hat{K}_1, \dots, \hat{K}_N).$$

The *slow* subsystem is then given by the link equations, once they are rewritten as

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau}_J. \quad (11.10)$$

To obtain the dynamics of the *fast* subsystem, the joint torque is differentiated twice, the motor and link accelerations are replaced from (11.9), and the above definition of $\hat{\mathbf{K}}$ is used. This leads to

$$\begin{aligned} \epsilon^2 \ddot{\boldsymbol{\tau}}_J &= \hat{\mathbf{K}} \{ \mathbf{B}^{-1} \boldsymbol{\tau} - [\mathbf{B}^{-1} + \mathbf{M}^{-1}(\mathbf{q})] \boldsymbol{\tau}_J \\ &\quad + \mathbf{M}^{-1}(\mathbf{q})[\mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q})] \}. \end{aligned} \quad (11.11)$$

For small ϵ , (11.10) and (11.11) represent a singularly perturbed system. The two separate time scales governing the slow and fast dynamics are t and $\sigma = t/\epsilon$, since

$$\epsilon^2 \ddot{\boldsymbol{\tau}}_J = \epsilon^2 \frac{d^2 \boldsymbol{\tau}_J}{dt^2} = \frac{d^2 \boldsymbol{\tau}_J}{d\sigma^2}.$$

This model serves as a basis for composite control schemes, where the control torque has the general form

$$\boldsymbol{\tau} = \boldsymbol{\tau}_s(\mathbf{q}, \dot{\mathbf{q}}, t) + \epsilon \boldsymbol{\tau}_f(\mathbf{q}, \dot{\mathbf{q}}, \boldsymbol{\tau}_J, \dot{\boldsymbol{\tau}}_J). \quad (11.12)$$

This includes a slow action $\boldsymbol{\tau}_s$, designed when neglecting joint elasticity, and an additional action $\boldsymbol{\tau}_f$ for locally stabilizing the fast flexible dynamics around a suitable manifold in the state space. It can be verified that, when setting $\epsilon = 0$ in (11.10)–(11.12), the equivalent rigid robot model is recovered as

$$[\mathbf{M}(\mathbf{q}) + \mathbf{B}]\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau}_s.$$

A similar singular perturbation model (and control design) can also be derived for robot manipulators with flexible links.

11.1.2 Inverse Dynamics

Given a desired motion of a robot, we wish to compute the nominal torque needed to reproduce this motion in ideal conditions (the inverse dynamics problem). Such nominal torque can be used as the feedforward term in a trajectory-tracking control law.

For rigid robots, the inverse dynamics is a straightforward algebraic computation obtained by replacing the desired motion of the generalized coordinates in the dynamic model. The minimum requirement for exact

reproduction is that the planned motion has a continuously differentiable desired velocity. For robots with elastic joints, a motion task can be conveniently expressed in terms of a desired link trajectory $\mathbf{q} = \mathbf{q}_d(t)$ (possibly obtained from the kinematic inversion of a desired motion in Cartesian space). The additional complexity lies in the fact that not all robot coordinates are directly assigned in this way, so that additional derivations should be performed. This will require some higher degree of smoothness of the desired trajectory $\mathbf{q}_d(t) \in [0, T]$, where the final time T may or may not be finite.

Reduced Model

Consider first the case of the reduced model (11.7) and set $\mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q})$ for compactness. By evaluating the link equations on the desired link motion

$$\mathbf{M}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K}\mathbf{q}_d = \mathbf{K}\boldsymbol{\theta}_d, \quad (11.13)$$

the nominal position $\boldsymbol{\theta}_d$ of the motors associated with the desired link motion is readily obtained. The nominal elastic torque at the joints is $\boldsymbol{\tau}_{J,d} = \mathbf{K}(\boldsymbol{\theta}_d - \mathbf{q}_d)$; note that, from (11.13), this quantity can be expressed as a function of \mathbf{q}_d , $\dot{\mathbf{q}}_d$, and $\ddot{\mathbf{q}}_d$, which is independent of \mathbf{K} . Differentiating (11.13) leads to the expression for the nominal motor velocity $\dot{\boldsymbol{\theta}}_d$,

$$\mathbf{M}(\mathbf{q}_d)\dot{\mathbf{q}}_d^{[3]} + \dot{\mathbf{M}}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \dot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K}\dot{\mathbf{q}}_d = \mathbf{K}\dot{\boldsymbol{\theta}}_d, \quad (11.14)$$

where the notation $\mathbf{y}^{[i]} = d^i\mathbf{y}/dt^i$ is used. Differentiating once more, we obtain

$$\begin{aligned} &\mathbf{M}(\mathbf{q}_d)\dot{\mathbf{q}}_d^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q}_d)\dot{\mathbf{q}}_d^{[3]} + \ddot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \\ &+ [\ddot{\mathbf{M}}(\mathbf{q}_d) + \mathbf{K}]\ddot{\mathbf{q}}_d = \mathbf{K}\ddot{\boldsymbol{\theta}}_d, \end{aligned} \quad (11.15)$$

to be used in the motor equations evaluated along the desired motion. After simplifications, the nominal torque is obtained as

$$\begin{aligned} \boldsymbol{\tau}_d = &[\mathbf{M}(\mathbf{q}_d) + \mathbf{B}]\ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \\ &+ \mathbf{BK}^{-1} \left[\mathbf{M}(\mathbf{q}_d)\dot{\mathbf{q}}_d^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q}_d)\dot{\mathbf{q}}_d^{[3]} \right. \\ &\left. + \ddot{\mathbf{M}}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \ddot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \right], \end{aligned} \quad (11.16)$$

where the extra contributions to the nominal torque of the rigid case due to joint elasticity can be clearly recognized. The evaluation of $\boldsymbol{\tau}_d$ involves the computation of first- and second-order partial derivatives of the dynamic model terms. For instance, one needs to compute

$$\dot{\mathbf{M}}[\mathbf{q}_d(t)] = \sum_{i=1}^N \frac{\partial \mathbf{M}_i(\mathbf{q})}{\partial \mathbf{q}} \bigg|_{\mathbf{q}=\mathbf{q}_d(t)} \dot{\mathbf{q}}_d(t) \mathbf{e}_i^T,$$

where \mathbf{e}_i is the i -th unit vector and \mathbf{M}_i is the i -th column of matrix $\mathbf{M}(\mathbf{q})$. This and other similar expressions can be obtained by symbolic manipulation software. From (11.16), it follows that the minimum requirement for the exact reproducibility of the desired motion is that $\mathbf{q}_d(t)$ admits a continuously differentiable jerk (i. e., that $\dot{\mathbf{q}}_d^{[4]}(t)$ exists in the time interval $[0, T]$). Such a smoother requirement should not come unexpected, in view of the flexible nature of the system.

Similarly to the rigid case, a recursive numerical Newton–Euler algorithm can be defined, which computes efficiently the inverse dynamics torque (11.16) in $O(N)$ asymptotic complexity. For the reduced model of robots with elastic joints, the algorithm involves forward recursion of motion variables up to the fourth differential order and backward recursion of second time derivatives of forces and torques.

Complete Model

Some more analysis is needed for the model (11.9). For ease of exposition, and without loss of generality, the case of a constant matrix \mathbf{S} is considered. When evaluating the link equations on the desired link motion

$$\mathbf{M}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{S}\ddot{\boldsymbol{\theta}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K}\mathbf{q}_d = \mathbf{K}\boldsymbol{\theta}_d, \quad (11.17)$$

the additional presence of the motor acceleration on the left-hand side does not allow solving directly for the motor position $\boldsymbol{\theta}_d$ as a function of $(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)$ only. However, the strictly upper triangular structure (11.5) of \mathbf{S} allows one to define $\boldsymbol{\theta}_d$ componentwise, using the scalar equations in (11.17) recursively. The N -th equation is in fact independent of $\ddot{\boldsymbol{\theta}}_d$,

$$\mathbf{M}_N^T(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{0}^T\ddot{\boldsymbol{\theta}}_d + n_N(\mathbf{q}_d, \dot{\mathbf{q}}_d) + K_N q_{d,N} = K_N \theta_{d,N},$$

so that this equation can be used to define

$$\theta_{d,N} = f_N(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)$$

and, after double differentiation, its second time derivative

$$\ddot{\theta}_{d,N} = f_N''(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d).$$

In the $(N-1)$ -th equation,

$$\begin{aligned} &\mathbf{M}_{N-1}^T(\mathbf{q}_d)\ddot{\mathbf{q}}_d + S_{N-1,N}\ddot{\theta}_{d,N} \\ &+ n_{N-1}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + K_{N-1}q_{d,N-1} = K_{N-1}\theta_{d,N-1}, \end{aligned}$$

the acceleration $\ddot{\theta}_{d,N}$ has already been determined in the previous step. Therefore, this equation can be used similarly to define

$$\theta_{d,N-1} = f_{N-1}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)$$

and, after two time differentiations, also

$$\ddot{\theta}_{d,N-1} = f''_{N-1}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[6]}).$$

Note that whenever $S_{N-1,N} = 0$, there will be no increase in the degree of the highest order derivatives of \mathbf{q}_d within the functional dependence of $\theta_{d,N-1}$. This argument also applies recursively to the following steps. Proceeding backward through the link equations, the scalar computations end up with the definition of

$$\theta_{d,1} = f_1(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[2N]})$$

and

$$\ddot{\theta}_{d,1} = f''_1(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[2(N+1)]}),$$

where the dependence on the highest possible differential degree of \mathbf{q}_d is shown. With $\ddot{\theta}_d = f''(\cdot)$ made available in this way, the nominal torque is finally computed from the motor equations, again evaluated along the desired motion. Using (11.17) to substitute for $\mathbf{K}(\theta_d - \mathbf{q}_d)$ yields

$$\begin{aligned} \boldsymbol{\tau}_d &= [\mathbf{M}(\mathbf{q}_d) + \mathbf{S}^T] \ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \\ &\quad + (\mathbf{B} + \mathbf{S}) \ddot{\theta}_d(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[2(N+1)]}). \end{aligned} \quad (11.18)$$

As a result, the presence of inertial motor-link couplings considerably increases the complexity of the solution to the inverse dynamics problem. The exact reproduction of a desired link trajectory by the nominal torque in (11.18) requires that $\mathbf{q}_d(t)$ has a continuously differentiable $(2N+1)$ -th time derivative (i.e., that $\mathbf{q}_d^{[2(N+1)]}(t)$ exists in the time interval $[0, T]$). For rest-to-rest motions, this implies a trajectory plan that imposes a very slow start and ending phases.

We finally remark that the possibility of expressing the evolution of the state and input of a system algebraically in terms of the evolution of an output variable (in our case \mathbf{q}) and a finite number of its derivatives is sometimes referred to as the *flatness* property. The above inverse dynamics analysis shows that \mathbf{q} is a flat output for robots with elastic joints modeled either by (11.7) or (11.9).

Note also that, when a *constant* \mathbf{q}_d is considered, these computations all provide the same condition for the associated motor position

$$\theta_d = \mathbf{q}_d + \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d) \quad (11.19)$$

and nominal static torque

$$\boldsymbol{\tau}_d = \mathbf{g}(\mathbf{q}_d). \quad (11.20)$$

Presence of Dissipative Terms

Inclusion of dissipative terms in the inverse dynamics deserves some additional comments. Any model of frictional effects acting on the motor side of the transmissions can be included in the computation without extra requirements. Friction at the link side should instead be described by a smooth model, because of the need to differentiate the link equations. Thus, some functional approximations may be needed (e.g., replacing discontinuous *sign* functions with hyperbolic tangents) before including this term in (11.13) or (11.17).

On the other hand, the presence of a nonnegligible spring damping \mathbf{D} in (11.8) changes the structure of the computations. While this reduces the order of the derivatives of \mathbf{q}_d involved, the problem itself will become nonalgebraic; in fact, the inverse system will require the use of the solution of a dynamical system, albeit a simple one.

Consider for instance the model (11.9), including now all the dissipative terms given in (11.8). When evaluating the link equations,

$$\begin{aligned} \mathbf{M}(\mathbf{q}_d) \ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + (\mathbf{D} + \mathbf{F}_q) \dot{\mathbf{q}}_d + \mathbf{K} \mathbf{q}_d \\ = \mathbf{D} \ddot{\theta}_d + \mathbf{K} \theta_d, \end{aligned} \quad (11.21)$$

the motor velocity $\dot{\theta}_d$ additionally appears on the right-hand side. Differentiating (11.21) leads to

$$\mathbf{D} \ddot{\theta}_d + \mathbf{K} \dot{\theta}_d = \mathbf{w}_d, \quad (11.22)$$

with

$$\begin{aligned} \mathbf{w}_d &= \mathbf{M}(\mathbf{q}_d) \mathbf{q}_d^{[3]} + [\dot{\mathbf{M}}(\mathbf{q}_d) + \mathbf{D} + \mathbf{F}_q] \ddot{\mathbf{q}}_d \\ &\quad + \dot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K} \dot{\mathbf{q}}_d. \end{aligned}$$

Equation (11.22) represents a first-order linear *asymptotically stable* dynamical system (internal dynamics), with state θ_d and forcing signal $\mathbf{w}_d(t)$. For a given $\dot{\theta}_d(0)$, its solution $\dot{\theta}_d(t)$ and the associated solution derivative $\ddot{\theta}_d(t)$ are needed to evaluate the nominal torque in the motor equations. This yields

$$\boldsymbol{\tau}_d = \mathbf{M}(\mathbf{q}_d) \ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{F}_q \dot{\mathbf{q}}_d + \mathbf{B} \ddot{\theta}_d + \mathbf{F}_\theta \dot{\theta}_d,$$

where (11.21) has been used to replace the term $\mathbf{D}(\dot{\theta}_d - \dot{\mathbf{q}}_d) + \mathbf{K}(\theta_d - \mathbf{q}_d)$. In this case, the desired link trajectory $\mathbf{q}_d(t)$ should have a continuously differentiable acceleration ($\mathbf{q}_d^{[3]}$ should exist, since it is used in the definition of \mathbf{w}_d). Note that any initialization $\dot{\theta}_d(0)$ of the internal dynamics (11.22) is feasible (i.e., it produces a specific torque profile $\boldsymbol{\tau}_d(t)$ yielding the same link

motion $\mathbf{q}_d(t)$, with the associated motor position $\theta_d(0)$ initialized from (11.21). Indeed, we should match the actual initial state of the robot. For instance, starting from an equilibrium state implies the unique choice $\theta_d(0) = \mathbf{0}$.

A similar procedure can also be applied to the complete model (11.7) in the presence of spring damping. Again a dynamical inverse system will be needed, while the smoothness requirement on $\mathbf{q}_d(t)$ would be even more dramatically reduced in that case.

We finally remark that, for robots with flexible links, the inverse dynamics problem gives also rise to an internal dynamics, independently of the presence of modal damping. Moreover, when specifying a desired motion for the tip of the flexible arm, the associated internal dynamics will be *unstable* and this critical issue has to be tackled to determine a feasible solution.

11.1.3 Regulation Control

We now consider the problem of controlling the motion of a robot with joint elasticity to a *constant* configuration. In this problem, no trajectory planning is involved and a feedback law should be found that achieves asymptotic stabilization of a desired closed-loop equilibrium. Global solutions (i. e., those valid when starting from any initial state) are indeed preferred.

From the analysis in the previous section, it should be clear that one needs to define only a constant reference \mathbf{q}_d (with $\dot{\mathbf{q}}_d(t) \equiv \mathbf{0}$) for the link coordinates.

From (11.19), a unique reference θ_d for the motor variables is in fact associated with the desired \mathbf{q}_d (which, in turn, may result from a desired pose of the robot end-effector). Furthermore, (11.20) provides the needed static torque to be applied at steady state by any feasible controller.

A major aspect of the presence of joint elasticity is that the feedback part of the control law can depend in general on *four* variables for each joint: the motor and link position, and the motor and link velocity. However, in most robots where joint elasticity is not explicitly considered in the system design, at most two sensors are available for measurement at the joints: a position sensor (e.g., an encoder) and, in some cases, a tachometer as a velocity sensor. When no velocity sensors are present, velocity is typically reconstructed by suitable numerical differentiation of high-resolution position measurements. Due to the presence of joint elasticity, the position/velocity quantities that are actually measured depend on where these sensors are mounted in the motor/transmission assembly.

A single link driven through an elastic joint is introduced as a paradigmatic case study to show what can be achieved using different sets of partial state measurements. This simple situation provides indications on how to handle the general multilink case.

In the absence of gravity, it will be shown that a proportional–derivative (PD) controller based only on motor measurements is sufficient to achieve the desired regulation task. In the presence of gravity, various gravity compensation schemes can be added to the PD feedback controller. These control results mimic the situation of robots with rigid joints, once the convenient quantities for use in the feedback have been identified.

Single Elastic Joint Example

Consider a single link rotating on a horizontal plane (thus, without gravity) and actuated with a motor through an elastic joint coupling (Fig. 11.4). When viscous friction on motor and link side as well as damping across the spring are included, the dynamic model is

$$M\ddot{q} + D(\dot{q} - \dot{\theta}) + K(q - \theta) + F_q\dot{q} = 0,$$

$$B\ddot{\theta} + D(\dot{\theta} - \dot{q}) + K(\theta - q) + F_\theta\dot{\theta} = \tau,$$

where the same, now scalar, notation of Sect. 11.1.1 has been used. Since this system is described by linear equations, Laplace transforms are used to derive the transfer functions of interest, namely from input torque to motor position

$$\frac{\theta(s)}{\tau(s)} = \frac{Ms^2 + (D + F_q)s + K}{\text{den}(s)},$$

Fig. 11.6 Bode diagrams of the torque to motor velocity transfer function

and from input torque to link position

$$\frac{q(s)}{\tau(s)} = \frac{Ds + K}{\text{den}(s)},$$

with the common denominator $\text{den}(s)$ given by

$$\begin{aligned} \text{den}(s) = & \left\{ MBs^3 + [M(D + F_\theta) + B(D + F_q)]s^2 \right. \\ & + [(M + B)K + (F_q + F_\theta)D + F_q F_\theta]s \\ & \left. + (F_q + F_\theta)K \right\} s. \end{aligned}$$

In the case of link position output, the transfer function has a larger relative degree (or pole-zero excess). Figures 11.6 and 11.7 show typical frequency responses in the two cases. For clarity, the outputs have been chosen at the velocity level. In the Bode diagram of the magnitude for the motor velocity output, note the presence of an antiresonance/resonance behavior. Similarly, there is a pure resonance (more pronounced for weak or zero spring damping D) for the link velocity output. The phase profile in Fig. 11.7, with a high-frequency lag of 270° , indicates the greater control difficulty encountered when closing the feedback loop on link quantities. In experimental tests on a robot joint, such plots are quite characteristic of the presence of concentrated joint elasticity and can be used to assess the relevance of this phenomenon and for identifying model parameters.

For the analysis of the stabilizing properties of different feedback arrangements, all dissipative effects will be neglected in the following ($D = F_q = F_\theta = 0$ is anyway the worst case). Consider first the transfer function relative to the motor position output

$$\left. \frac{\theta(s)}{\tau(s)} \right|_{\text{no diss}} = \frac{Ms^2 + K}{[MBs^2 + (M + B)K]s^2}. \quad (11.23)$$

Apart from a double pole at the origin, this transfer function has a pair of imaginary zeros and poles, with the zero pair occurring at the so-called locked frequency

$$\omega_1 = \sqrt{\frac{K}{M}},$$

which characterizes the oscillations occurring when the motor is locked ($\theta \equiv 0$), e.g., by a high-gain positional feedback. This frequency is used to assess the performance limit of a simple PD control for the motor variables. In order to achieve enough damping in the closed-loop system, the bandwidth should be limited, as a rule of thumb, to one-third of ω_1 . Faster transients can be achieved only by taking into account the fourth-order dynamics of the elastic joint assembly. Note also

Fig. 11.7 Bode diagrams of the torque to link velocity transfer function

that the frequency of the zero pair is always *lower* than that of the pole pair in (11.23). This is related to the *passivity* of the mapping from torque to motor velocity, a property useful for stability and robust or adaptive control design.

Since the control objective is to regulate the link position output, we are also interested in the open-loop transfer function

$$\left. \frac{q(s)}{\tau(s)} \right|_{\text{no diss}} = \frac{K}{[MBs^2 + (M + B)K]s^2}. \quad (11.24)$$

This transfer function has *no zeros* (in fact, for this to happen it is sufficient that $D = 0$) so that the relative degree is now four, the maximum possible. We shall see that the nonlinear counterpart of the absence of zeros in (11.24) will play a relevant role also for trajectory control in the multilink case of robots with elastic joints.

It is worth mentioning that this situation is completely different from the case in which the elastic spring would be moved out of the joint and placed anywhere along the link – a simple one-mode approximate model of link flexibility. In that case, the analogous transfer function will possess a negative and a positive real zero, symmetrically placed w.r.t. the origin (a *non-minimum-phase* system). This indicates the criticality of a direct inversion of the system input–output map for the execution of a desired link trajectory.

With the desired position given in terms of the link variable q_d , the most natural choice for the design of

a linear stabilizing feedback using one position and one velocity variable, is to close a PD loop from the link variables,

$$\tau = u_q - (K_{P,q}q + K_{D,q}\dot{q}) , \quad (11.25)$$

with position and velocity gains $K_{P,q}$ and $K_{D,q}$, and with $u_q = K_{P,q}q_d$ being the external input used for defining the set point. It is easy to verify that the closed-loop poles will be unstable no matter how the gains are chosen, so that error feedback from link variables alone should be avoided. In a similar way, also the combination of motor position and link velocity feedback is always unstable.

Another mixed feedback strategy is to use link position and motor velocity

$$\tau = u_q - (K_{P,q}q + K_{D,m}\dot{\theta}) . \quad (11.26)$$

This combination corresponds, e.g., to the case of a tachometer integrated in a direct-current (DC) motor and of an optical encoder placed on the load shaft for sensing its position (without any knowledge about the relevance of joint elasticity). Use of (11.26) leads to the closed-loop characteristic equation

$$BMs^4 + MK_{D,m}s^3 + (B + M)Ks^2 + KK_{D,m}s + KK_{P,q} = 0 .$$

Using Routh's criterion, asymptotic stability occurs if and only if the motor velocity gain $K_{D,m} > 0$ and the link position gain satisfies $0 < K_{P,q} < K$, i.e., the proportional feedback should not *override* the spring stiffness. The existence of such an upper bound limits the usefulness of this scheme.

Finally, consider performing feedback from the motor variables

$$\tau = u_\theta - (K_{P,m}\theta + K_{D,m}\dot{\theta}) , \quad (11.27)$$

with $u_\theta = K_{P,m}\theta_d = K_{P,m}q_d$ (due to the absence of gravity). The closed-loop system will be asymptotically stable provided that both $K_{P,m}$ and $K_{D,m}$ are strictly positive (and otherwise arbitrarily large). This favorable situation lends itself to a convenient generalization in the multilink case.

Note that other partial state feedback combinations would be possible, depending on the available sensing devices. For instance, mounting a strain gauge on the transmission shaft provides a direct measure of the elastic torque $\tau_j = K(\theta - q)$ for control use. Strain gauges are also useful sensors for flexible links. Indeed, full-state feedback may be designed so as to guarantee

asymptotic stability and improve the transient behavior considerably; however, this would be obtained at the cost of additional sensors and requires proper tuning of the four gains.

PD Control Using only Motor Variables

For the general multilink case in the absence of gravity, consider the PD control law based on motor position and velocity feedback

$$\tau = \mathbf{K}_P(\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{K}_D\dot{\boldsymbol{\theta}} , \quad (11.28)$$

with symmetric (typically, diagonal) positive-definite gain matrices \mathbf{K}_P and \mathbf{K}_D . Since $\mathbf{g}(\mathbf{q}) \equiv \mathbf{0}$, it follows from (11.19) that the reference value for the motor position is $\boldsymbol{\theta}_d = \mathbf{q}_d$ (neither a joint deflection is present nor an input torque is needed at steady state).

The control law (11.28) globally asymptotically stabilizes the desired equilibrium state $\mathbf{q} = \boldsymbol{\theta} = \mathbf{q}_d$, $\dot{\mathbf{q}} = \dot{\boldsymbol{\theta}} = \mathbf{0}$. This can be shown through a Lyapunov argument, completed by the application of La Salle's theorem. In fact, a candidate Lyapunov function is given by the sum of the total energy of the system (kinetic plus elastic potential) and of the control energy due to the proportional term (a virtual elastic potential energy)

$$V = \frac{1}{2} \dot{\boldsymbol{\theta}}^T \mathcal{M}(\boldsymbol{\theta}) \dot{\boldsymbol{\theta}} + \frac{1}{2} (\mathbf{q} - \boldsymbol{\theta})^T \mathbf{K} (\mathbf{q} - \boldsymbol{\theta}) + \frac{1}{2} (\boldsymbol{\theta}_d - \boldsymbol{\theta})^T \mathbf{K}_P (\boldsymbol{\theta}_d - \boldsymbol{\theta}) \geq 0 . \quad (11.29)$$

Computing the time derivative of V along the trajectories of the closed-loop system given by (11.7) (or (11.9)) and (11.28), and taking into account the skew-symmetry of $\dot{\mathcal{M}} - 2\mathbf{C}$, leads to

$$\dot{V} = -\dot{\boldsymbol{\theta}}^T \mathbf{K}_D \dot{\boldsymbol{\theta}} \leq 0 .$$

The inclusion of dissipative terms (viscous friction and spring damping) would render \dot{V} even more negative-semidefinite. The analysis is completed by verifying that the maximum invariant set contained in the set of states such that $\dot{V} = 0$ (i.e., those with $\dot{\boldsymbol{\theta}} = \mathbf{0}$) collapses into the desired unique equilibrium state.

We point out that an identical control law is able to globally regulate, in the absence of gravity, robots with flexible links to a desired joint configuration. In that case, $\boldsymbol{\theta}$ in (11.28) would be the rigid coordinates at the base of the flexible links of the robot.

PD with Constant Gravity Compensation

The presence of gravity requires the addition of some form of gravity compensation to the PD action (11.28).

Moreover, this will typically need an additional structural assumption and may demand some caution in the selection of the control gains.

Before proceeding, we recall a basic property of the gravity vector $\mathbf{g}(\mathbf{q})$ (under assumption **A2**, the gravity vector in (11.7) is the same appearing in the dynamics of the equivalent rigid robot). For robots with rotational joints, elastic or not, a positive constant α exists such that

$$\left\| \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \right\| \leq \alpha, \quad \forall \mathbf{q} \in \mathbb{R}^N. \quad (11.30)$$

The norm of a matrix $\mathbf{A}(\mathbf{q})$ is that induced by the Euclidean norm for vectors, i.e.,

$$\|\mathbf{A}\| = \sqrt{\lambda_{\max}(\mathbf{A}^T \mathbf{A})}.$$

Inequality (11.30) implies that

$$\|\mathbf{g}(\mathbf{q}_1) - \mathbf{g}(\mathbf{q}_2)\| \leq \alpha \|\mathbf{q}_1 - \mathbf{q}_2\|, \quad \forall \mathbf{q}_1, \mathbf{q}_2 \in \mathbb{R}^N. \quad (11.31)$$

In common practice, robot joints are never unrealistically soft. More precisely, they are stiff enough to have, under the load of the robot's own weight, a *unique* equilibrium link position \mathbf{q}_e associated with any assigned motor position $\boldsymbol{\theta}_e$ – the reverse of the relationship expressed by (11.19). This situation is by no means restrictive, but will be stated for clarity as a further modeling assumption:

A5 The lowest joint stiffness is larger than the upper bound on the gradient of gravity forces acting on the robot, or

$$\min_{i=1, \dots, N} K_i > \alpha.$$

The simplest modification for handling the presence of gravity is to consider the addition of a constant term that compensates exactly the gravity load at the desired steady state. According to (11.19) and (11.20), the control law (11.28) is then modified to

$$\boldsymbol{\tau} = \mathbf{K}_p(\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{K}_D \dot{\boldsymbol{\theta}} + \mathbf{g}(\mathbf{q}_d), \quad (11.32)$$

with symmetric, typically diagonal, $\mathbf{K}_p > \mathbf{0}$ (as a minimum) and $\mathbf{K}_D > \mathbf{0}$, and with the motor reference given by $\boldsymbol{\theta}_d = \mathbf{q}_d + \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d)$.

A sufficient condition guaranteeing that $\mathbf{q} = \mathbf{q}_d$, $\boldsymbol{\theta} = \boldsymbol{\theta}_d$, $\dot{\mathbf{q}} = \dot{\boldsymbol{\theta}} = \mathbf{0}$ will be the unique globally asymptotically stable equilibrium for the system (11.7) under the control law (11.32) is that

$$\lambda_{\min} \left[\begin{pmatrix} \mathbf{K} & -\mathbf{K} \\ -\mathbf{K} & \mathbf{K} + \mathbf{K}_p \end{pmatrix} \right] > \alpha, \quad (11.33)$$

with α defined in (11.30). Taking into account the diagonal structure of \mathbf{K} and \mathbf{K}_p , and thanks to assumption **A5**, it is always possible to fulfill this condition by increasing the smallest proportional gain in the controller (or, the smallest eigenvalue of \mathbf{K}_p if this matrix has not been chosen diagonal).

In the following, we sketch the motivation for this condition and the associated proof of asymptotic stability. The equilibrium configurations of the closed-loop system are the solutions of

$$\begin{aligned} \mathbf{K}(\mathbf{q} - \boldsymbol{\theta}) + \mathbf{g}(\mathbf{q}) &= \mathbf{0}, \\ \mathbf{K}(\boldsymbol{\theta} - \mathbf{q}) - \mathbf{K}_p(\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{g}(\mathbf{q}_d) &= \mathbf{0}. \end{aligned}$$

Indeed, the pair $(\mathbf{q}_d, \boldsymbol{\theta}_d)$ satisfies these equations. However, in order to obtain a global result one should guarantee that this pair is the unique solution. Therefore, recalling (11.19), the null term $\mathbf{K}(\boldsymbol{\theta}_d - \mathbf{q}_d) - \mathbf{g}(\mathbf{q}_d)$ can be added/subtracted to both equations to obtain

$$\begin{aligned} \mathbf{K}(\mathbf{q} - \mathbf{q}_d) - \mathbf{K}(\boldsymbol{\theta} - \boldsymbol{\theta}_d) &= \mathbf{g}(\mathbf{q}_d) - \mathbf{g}(\mathbf{q}) \\ -\mathbf{K}(\mathbf{q} - \mathbf{q}_d) + (\mathbf{K} + \mathbf{K}_p)(\boldsymbol{\theta} - \boldsymbol{\theta}_d) &= \mathbf{0}, \end{aligned}$$

where the matrix in condition (11.33) can be clearly recognized. Taking the norms of terms on both sides and bounding gravity terms using (11.31), the introduced condition (11.33) implies that the pair $(\mathbf{q}_d, \boldsymbol{\theta}_d)$ is in fact the unique equilibrium. To show asymptotic stability, a candidate Lyapunov function is built based on the one introduced in (11.29) in the absence of gravity

$$\begin{aligned} V_{g1} &= V + \mathcal{U}_{\text{grav}}(\mathbf{q}) - \mathcal{U}_{\text{grav}}(\mathbf{q}_d) - (\mathbf{q} - \mathbf{q}_d)^T \mathbf{g}(\mathbf{q}_d) \\ &\quad - \frac{1}{2} \mathbf{g}^T(\mathbf{q}_d) \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d) \geq 0. \end{aligned} \quad (11.34)$$

The positive-definiteness of V_{g1} and the fact that its unique minimum is at the desired state are again implied by condition (11.33). (The last constant term in (11.34) is used to set to zero the minimum value of V_{g1} at the equilibrium.). By the usual computations, it follows that $\dot{V}_{g1} = -\dot{\boldsymbol{\theta}}^T \mathbf{K}_D \dot{\boldsymbol{\theta}} \leq 0$ and the result is obtained applying La Salle's theorem.

The control law (11.32) is based only on the knowledge of the gravity term $\mathbf{g}(\mathbf{q}_d)$ and of the joint stiffness \mathbf{K} . The latter appears in fact in the definition of the motor position reference $\boldsymbol{\theta}_d$. Uncertainties in the gravitational term $\mathbf{g}(\mathbf{q}_d)$ and in the joint stiffness \mathbf{K} affect the performance of the controller. Still, the existence of a unique closed-loop equilibrium and its asymptotic stability are preserved when the gravity bound by α is still correct and condition (11.33) holds for the true stiffness

values. Indeed, the robot will converge to an equilibrium that is different from the desired one – the better the estimates $\hat{\mathbf{K}}$ and $\hat{\mathbf{g}}(\mathbf{q}_d)$ used, the closer the actual equilibrium will be to the desired one.

PD with Online Gravity Compensation

Similarly to the rigid robot case, a better transient behavior is expected if gravity compensation (or, more precisely, its perfect cancellation) is performed at all configurations during motion. However, the gravity vector in (11.7) depends on the link variables \mathbf{q} , which are assumed not to be measurable at this stage. It is easy to see that using $\mathbf{g}(\boldsymbol{\theta})$, with the measured motor positions in place of the link positions, leads in general to an incorrect closed-loop equilibrium. Moreover, even if \mathbf{q} were available, adding $\mathbf{g}(\mathbf{q})$ to a motor PD error feedback has no guarantee of success because this compensation, which appears in the motor equation, does not instantaneously cancel the gravity load acting on the links.

With this in mind, a PD control with *online* gravity compensation can be introduced as follows. Define the variable

$$\tilde{\boldsymbol{\theta}} = \boldsymbol{\theta} - \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d), \quad (11.35)$$

which is a *gravity-biased* modification of the measured motor position $\boldsymbol{\theta}$, and let

$$\boldsymbol{\tau} = \mathbf{K}_P (\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{K}_D \dot{\boldsymbol{\theta}} + \mathbf{g}(\tilde{\boldsymbol{\theta}}), \quad (11.36)$$

where $\mathbf{K}_P > \mathbf{0}$ and $\mathbf{K}_D > \mathbf{0}$ are both symmetric (and typically diagonal) matrices. The control law (11.36) can still be implemented using only motor variables. The term $\mathbf{g}(\tilde{\boldsymbol{\theta}})$ provides only an approximate cancellation (though, of a large part) of gravity during motion, but leads to the correct gravity compensation at steady state. In fact, by using (11.19) and (11.35), it follows that

$$\tilde{\boldsymbol{\theta}}_d := \boldsymbol{\theta}_d - \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d) = \mathbf{q}_d,$$

so that $\mathbf{g}(\tilde{\boldsymbol{\theta}}_d) = \mathbf{g}(\mathbf{q}_d)$.

Global asymptotic stability of the desired equilibrium can be guaranteed under the same condition (11.33) used for the constant gravity compensation case. A slightly different Lyapunov candidate is defined, starting again from the one in (11.29), as

$$\begin{aligned} V_{g2} &= V + \mathcal{U}_{\text{grav}}(\mathbf{q}) - \mathcal{U}_{\text{grav}}(\tilde{\boldsymbol{\theta}}) \\ &\quad - \frac{1}{2} \mathbf{g}^T(\mathbf{q}_d) \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d) \geq 0, \end{aligned}$$

to be compared with (11.34).

The use of an online gravity compensation scheme typically provides a smoother time course and a noticeable reduction of the positional transient errors, with no additional control effort in terms of peak and average torques. We note that choices of low position gains, even when largely violating the sufficient condition (11.33) for stability, may still work, contrary to the case of constant gravity compensation. However even for increasing values of joint stiffness, in the limit for $\mathbf{K} \rightarrow \infty$, the range of feasible values of \mathbf{K}_P that guarantee exact regulation does not extend down to zero.

A possibility to refine the previous online gravity compensation scheme, again based only on motor position measurement, is offered by the use of a fast iterative algorithm that elaborates the measure $\boldsymbol{\theta}$ in order to generate a quasistatic estimate $\bar{\mathbf{q}}(\boldsymbol{\theta})$ of the current (unmeasured) \mathbf{q} . In fact, in any steady-state configuration $(\mathbf{q}_s, \boldsymbol{\theta}_s)$, a direct mapping is defined from \mathbf{q}_s to $\boldsymbol{\theta}_s$

$$\boldsymbol{\theta}_s = \mathbf{h}_g(\mathbf{q}_s) := \mathbf{q}_s + \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_s).$$

Assumption A5 is sufficient to guarantee the existence and uniqueness also of the inverse mapping $\mathbf{q}_s = \mathbf{h}_g^{-1}(\boldsymbol{\theta}_s)$. For a measured $\boldsymbol{\theta}$, the function

$$\mathbf{q} = \mathbf{T}(\boldsymbol{\theta}) := \boldsymbol{\theta} - \mathbf{K}^{-1} \mathbf{g}(\boldsymbol{\theta})$$

is then a *contraction mapping* and the iteration

$$\mathbf{q}_{i+1} = \mathbf{T}(\mathbf{q}_i), \quad i = 0, 1, 2, \dots$$

will converge to the unique fixed point of this mapping, which is exactly the value $\bar{\mathbf{q}}(\boldsymbol{\theta}) = \mathbf{h}_g^{-1}(\boldsymbol{\theta})$. A suitable initialization for \mathbf{q}_0 is either the measured $\boldsymbol{\theta}$ or the value $\bar{\mathbf{q}}$ computed at the previous sampling instant. In this way, just two or three iterations are needed to obtain sufficient accuracy and this is fast enough to be implemented within a sensing/control sampling interval of a digital robot controller. With this iterative scheme running in the background, the regulation control law becomes

$$\boldsymbol{\tau} = \mathbf{K}_P (\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{K}_D \dot{\boldsymbol{\theta}} + \mathbf{g}(\bar{\mathbf{q}}(\boldsymbol{\theta})), \quad (11.37)$$

with symmetric (diagonal) $\mathbf{K}_P > \mathbf{0}$ and $\mathbf{K}_D > \mathbf{0}$. A proof of the global asymptotic stability of this control scheme can be given by further modifying the previous Lyapunov candidates. The advantage of (11.37) is that any positive value of the feedback gain \mathbf{K}_P is allowed, thus recovering in full the operative working conditions of the rigid case with exact gravity cancellation.

With reference to the reduced model (11.9), a further improvement can be obtained via a nonlinear PD-like controller that removes completely the gravity from

the actual motion of the robot links. For this, consider the control law

$$\begin{aligned}\tau = & \mathbf{K}_P[\mathbf{q}_d - \boldsymbol{\theta} + \mathbf{K}^{-1}\mathbf{g}(\mathbf{q})] - \mathbf{K}_D(\dot{\boldsymbol{\theta}} - \mathbf{K}^{-1}\dot{\mathbf{g}}(\mathbf{q})) \\ & + \mathbf{g}(\mathbf{q}) + \mathbf{B}\mathbf{K}^{-1}\ddot{\mathbf{g}}(\mathbf{q})\end{aligned}\quad (11.38)$$

with symmetric (diagonal) $\mathbf{K}_P > 0$ and $\mathbf{K}_D > 0$. The last two terms are those needed to cancel both static and dynamic effects due to gravity. Even when assumption **A5** does not hold, the control law (11.38) guarantees global asymptotic stability of the desired equilibrium state. This result is a byproduct of feedback linearization design (Sect. 11.1.4), though much simpler than the complete one, and can be proven using again a Lyapunov analysis. Since a lower bound on the joint stiffness is not required (the joints may be arbitrarily soft), the same approach can be used also for robots using variable stiffness actuation (VSA). The price to pay is that an estimate of the link acceleration $\ddot{\mathbf{q}}$ is needed when computing the term $\ddot{\mathbf{g}}$ in (11.38).

The two online gravity compensation schemes (11.36) and (11.37) realize a *compliance control* in the joint space with only motor measurements. The same idea can also be extended to the case of Cartesian compliance control by evaluating the direct kinematics and the Jacobian (transpose) of the robot arm with $\boldsymbol{\theta}$ or, respectively, $\bar{\mathbf{q}}(\boldsymbol{\theta})$ in place of \mathbf{q} . The role of a damping action within a compliance/impedance control scheme can be clearly understood when looking at  VIDEO 133 and  VIDEO 134.

Full-State Feedback

When the feedback law is based on a full set of measurements of the robot state, the transient performance of regulation control laws can be improved. Taking advantage of the availability of a joint torque sensor, we present a convenient design for the reduced model (11.9) of robots with elastic joints, including spring damping as a dissipation effect. Full-state feedback can be obtained in two phases, by combining a preliminary torque feedback with the motor feedback law in (11.28).

Using $\tau_J = \mathbf{K}(\boldsymbol{\theta} - \mathbf{q})$, the motor equation can be rewritten as

$$\mathbf{B}\ddot{\boldsymbol{\theta}} + \tau_J + \mathbf{D}\mathbf{K}^{-1}\dot{\tau}_J = \tau.$$

The joint torque feedback

$$\tau = \mathbf{B}\mathbf{B}_\theta^{-1}\mathbf{u} + (\mathbf{I} - \mathbf{B}\mathbf{B}_\theta^{-1})(\tau_J + \mathbf{D}\mathbf{K}^{-1}\dot{\tau}_J), \quad (11.39)$$

where \mathbf{u} is an auxiliary input to be designed, transforms the motor equations into

$$\mathbf{B}_\theta\ddot{\boldsymbol{\theta}} + \tau_J + \mathbf{D}\mathbf{K}^{-1}\dot{\tau}_J = \mathbf{u}.$$

In this way, the apparent motor inertia can be reduced to a desired, arbitrary small value \mathbf{B}_θ , with clear benefits in terms of vibration damping. For instance in the linear and scalar case, a very small B shifts the pair of complex poles in (11.23) to a very high frequency, with the joint behaving almost as a rigid one.

Setting now

$$\mathbf{u} = \mathbf{K}_{P,\theta}(\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{K}_{D,\theta}\dot{\boldsymbol{\theta}} + \mathbf{g}(\mathbf{q}_d)$$

in (11.39) leads to the state feedback controller

$$\begin{aligned}\tau = & \mathbf{K}_P(\boldsymbol{\theta}_d - \boldsymbol{\theta}) - \mathbf{K}_D\dot{\boldsymbol{\theta}} + \mathbf{K}_T[\mathbf{g}(\mathbf{q}_d) - \tau_J] \\ & - \mathbf{K}_S\dot{\tau}_J + \mathbf{g}(\mathbf{q}_d),\end{aligned}\quad (11.40)$$

with gains

$$\begin{aligned}\mathbf{K}_P &= \mathbf{B}\mathbf{B}_\theta^{-1}\mathbf{K}_{P,\theta}, \\ \mathbf{K}_D &= \mathbf{B}\mathbf{B}_\theta^{-1}\mathbf{K}_{D,\theta}, \\ \mathbf{K}_T &= \mathbf{B}\mathbf{B}_\theta^{-1} - \mathbf{I} \\ \mathbf{K}_S &= (\mathbf{B}\mathbf{B}_\theta^{-1} - \mathbf{I})\mathbf{D}\mathbf{K}^{-1}.\end{aligned}$$

Indeed, the law (11.40) can also be rewritten in terms of $(\boldsymbol{\theta}, \mathbf{q}, \dot{\boldsymbol{\theta}}, \dot{\mathbf{q}})$, if the torque sensor is not available. However, keeping this structure of the gains preserves the interesting physical interpretation of what the full-state feedback controller is able to achieve.

11.1.4 Trajectory Tracking

As for rigid robots, the problem of tracking desired time-varying trajectories for robots with elastic joints is harder than that of achieving constant regulation. In general, solving this problem requires the use of full-state feedback and knowledge of all the terms in the dynamic model.

Under these conditions, we shall focus on the *feedback linearization* approach, namely a nonlinear state feedback law that leads to a closed-loop system with decoupled and exactly linear behavior for all the N joints of the robot (in fact, the link variables \mathbf{q}). The tracking errors along the reference trajectory are forced to be *globally exponentially stable*, with a decaying rate that can be directly specified through the choice of the scalar feedback gains in the controller. This fundamental result is the direct extension of the well-known *computed torque* method for rigid robots. Because of its relevant properties, the feedback linearization approach

can be used as a reference to assess the performance of any other trajectory tracking control law, which may possibly be designed using less/approximate model information and/or only partial-state feedback.

However, in the presence of joint elasticity, the design of a feedback linearization law is not straightforward. Furthermore, as soon as $\mathbf{S} \neq \mathbf{0}$, the dynamic model (11.7) will not satisfy the necessary conditions for exact linearization (nor those for input–output decoupling) when only a *static* (or, instantaneous) feedback law from the full state is allowed. Therefore, we will restrict our attention to the more tractable case of the reduced dynamic model (11.9) and sketch only briefly the more general picture.

As a second much simpler approach to trajectory tracking problems, we also present a *linear control design* that makes use of a model-based feedforward command and a precomputed state reference trajectory, as obtained from the inverse dynamics in Sect. 11.1.2, with the addition of a linear feedback from the full state. In this case, convergence to the desired trajectory is only locally guaranteed, i. e., the tracking errors should be small enough, but the control implementation is straightforward and the real-time computational burden is considerably reduced.

Feedback Linearization

Consider the reduced model (11.9) and let the desired motion be specified by a smooth reference trajectory $\mathbf{q}_d(t)$ for the robot links. The control design will proceed by system inversion, in a similar way to the inverse dynamics computations of Sect. 11.1.2 but using now the current measures of the state variables $(\mathbf{q}, \boldsymbol{\theta}, \dot{\mathbf{q}}, \dot{\boldsymbol{\theta}})$ instead of the reference state evolution $(\mathbf{q}_d, \boldsymbol{\theta}_d, \dot{\mathbf{q}}_d, \dot{\boldsymbol{\theta}}_d)$. Notably, there is no need to transform the robot equations into their state-space description, which is the standard form used in control design for general nonlinear systems; we will use the robot model directly in its second-order differential form (typical of mechanical systems).

The outcome of the inversion procedure will be the definition of a torque $\boldsymbol{\tau}$, in the form of a static state feedback control law, which cancels the original robot dynamics and replaces it with a desired linear and decoupled one of suitable differential order. In this sense, the control law *stiffens* the dynamics of the robot with elastic joints, irrespective of the fact that \mathbf{K} is already relatively large (stiff joint) or small (soft joint). The feasibility of inverting the system from the chosen output \mathbf{q} without causing instability problems (related to the presence of unobservable dynamics in the closed-loop system, after cancellation) is a relevant property of robots with elastic joints. In fact, this is the direct generalization to the nonlinear multiple-input multiple-

output (MIMO) case of the possibility of inverting a scalar transfer function in the absence of zeros (see also the considerations made on (11.24)).

Rewrite the link equation in the compact form

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}(\mathbf{q} - \boldsymbol{\theta}) = \mathbf{0}. \quad (11.41)$$

None of the above quantities depends instantaneously on the input torque $\boldsymbol{\tau}$. Therefore, we can differentiate once w.r.t. time and obtain

$$\mathbf{M}(\mathbf{q})\mathbf{q}^{[3]} + \dot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}(\dot{\mathbf{q}} - \dot{\boldsymbol{\theta}}) = \mathbf{0}. \quad (11.42)$$

Proceeding one step further leads to

$$\begin{aligned} \mathbf{M}(\mathbf{q})\mathbf{q}^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q})\mathbf{q}^{[3]} + \ddot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} \\ + \ddot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}(\ddot{\mathbf{q}} - \ddot{\boldsymbol{\theta}}) = \mathbf{0}, \end{aligned} \quad (11.43)$$

where $\ddot{\boldsymbol{\theta}}$ now appears. The motor acceleration is at the same differential level of $\boldsymbol{\tau}$ in the motor equation

$$\mathbf{B}\ddot{\boldsymbol{\theta}} + \mathbf{K}(\boldsymbol{\theta} - \mathbf{q}) = \boldsymbol{\tau}, \quad (11.44)$$

and thus, replacing $\ddot{\boldsymbol{\theta}}$ from (11.44), we get

$$\begin{aligned} \mathbf{M}(\mathbf{q})\mathbf{q}^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q})\mathbf{q}^{[3]} + \ddot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + \ddot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}\ddot{\mathbf{q}} \\ = \mathbf{KB}^{-1} [\boldsymbol{\tau} - \mathbf{K}(\boldsymbol{\theta} - \mathbf{q})]. \end{aligned} \quad (11.45)$$

We note that, using (11.41), the last term $\mathbf{K}(\boldsymbol{\theta} - \mathbf{q})$ in (11.45) may also be replaced by $\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})$.

Since the matrix $\mathbf{A}(\mathbf{q}) = \mathbf{M}^{-1}(\mathbf{q})\mathbf{KB}^{-1}$ is always nonsingular, an arbitrary value \mathbf{v} can be assigned to the fourth derivative of \mathbf{q} by a suitable choice of the input torque $\boldsymbol{\tau}$. The matrix $\mathbf{A}(\mathbf{q})$ is the so-called decoupling matrix of the system and its nonsingularity is a necessary and sufficient condition for imposing a decoupled input–output behavior by nonlinear static state feedback. Moreover, (11.45) indicates that each component q_i of \mathbf{q} needs to be differentiated $r_i = 4$ times in order to be algebraically related to the input torque $\boldsymbol{\tau}$ (r_i is the *relative degree* of q_i , when this is chosen as a system output). Since there are N link variables, the total sum of the relative degrees is $4N$, equal to the dimension of the state of a robot with elastic joints. All these facts taken together lead to the conclusion that, when inverting (11.45) to determine the input $\boldsymbol{\tau}$ that imposes $\mathbf{q}^{[4]} = \mathbf{v}$, there will be no dynamics left other than the one appearing in the closed-loop input–output map.

Therefore, choose

$$\begin{aligned} \boldsymbol{\tau} = \mathbf{BK}^{-1} \left[\mathbf{M}(\mathbf{q})\mathbf{v} + \boldsymbol{\alpha} \left(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \mathbf{q}^{[3]} \right) \right] \\ + [\mathbf{M}(\mathbf{q}) + \mathbf{B}]\ddot{\mathbf{q}} + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}), \end{aligned} \quad (11.46)$$

with

$$\alpha(q, \dot{q}, \ddot{q}, q^{[3]}) = \ddot{M}(q)\ddot{q} + 2\dot{M}(q)\dot{q}^{[3]} + \ddot{n}(q, \dot{q}),$$

where the terms in α have been ordered according to the dependence on increasing orders of derivatives of q . It is easy to verify that the control law (11.46) leads to a closed-loop system fully described by

$$q^{[4]} = v, \quad (11.47)$$

i.e., chains of four input–output integrators from each auxiliary input v_i to each link position output q_i , for $i = 1, \dots, N$. Thus, the robot system has been exactly linearized and decoupled by the nonlinear feedback law (11.46). The improvement in performance can be appreciated in a comparative way by looking at [VIDEO 135](#) and [VIDEO 770](#).

The complete control law (11.46) is expressed as a function of the so-called *linearizing* coordinates $(q, \dot{q}, \ddot{q}, q^{[3]})$ only. This has led to some misunderstandings in the past, as it seemed that the feedback linearization approach for robots with elastic joints would need direct measures of the link acceleration \ddot{q} and jerk $q^{[3]}$, which are impossible to obtain with currently available sensors (or would require multiple numerical differentiations of position measures in real time, with critical noise problems).

When considering the latest technology in the field, it is now feasible to have a set of sensors for elastic joints measuring in a reliable and accurate way the motor position θ (and, possibly, also its velocity $\dot{\theta}$), the joint torque $\tau_J = K(\theta - q)$, as well as the link position q . For instance, this is the arrangement of sensors available at each joint of the *LWR-III* lightweight manipulator, where expressly designed high-resolution incremental encoders of the magneto-resistive type are used for the motor position, joint torque sensing is based on a full bridge of strain gauges, and a high-end capacitive potentiometer is used for the absolute link position (Fig. 11.8). Therefore, only one numerical differentiation is needed in order to obtain a good estimate of \dot{q} and/or $\dot{\tau}_J$ as well. Note that, depending on the specific sensor resolution, it may also be convenient to evaluate q using the measures of θ and τ_J as $\theta - K^{-1}\tau_J$.

With this in mind, it is easy to see that the following three sets of $4N$ variables

$$(q, \dot{q}, \ddot{q}, q^{[3]}), \quad (q, \theta, \dot{q}, \dot{\theta}), \quad (q, \tau_J, \dot{q}, \dot{\tau}_J)$$

are all equivalent state variables for a robot with elastic joints, related by globally invertible transformations. Therefore, under the assumption that the dynamic

Fig. 11.8 Exploded view of a joint of the *DLR LWR-III* lightweight manipulator and its sensor suite

model is available, we can completely rewrite the feedback linearizing control law (11.46) in terms of the more *conventional* state $(q, \theta, \dot{q}, \dot{\theta})$ or, taking advantage of a joint torque sensor, in terms of $(q, \tau_J, \dot{q}, \dot{\tau}_J)$. In particular, as a byproduct of (11.41) and (11.42), we have

$$\begin{aligned} \ddot{q} &= M^{-1}(q) [K(\theta - q) - n(q, \dot{q})] \\ &= M^{-1}(q) [\tau_J - n(q, \dot{q})], \end{aligned} \quad (11.48)$$

and

$$\begin{aligned} q^{[3]} &= M^{-1}(q) [K(\dot{\theta} - \dot{q}) - \dot{M}(q)\ddot{q} - \dot{n}(q, \dot{q})] \\ &= M^{-1}(q) [\dot{\tau}_J - \dot{M}(q)\ddot{q} - \dot{n}(q, \dot{q})], \end{aligned} \quad (11.49)$$

where the acceleration \ddot{q} appearing in (11.49) has already been computed through (11.48). Therefore, the exact linearizing and decoupling control law can be rewritten in terms of a static state feedback law of the form $\tau = \tau(q, \theta, \dot{q}, \dot{\theta}, v)$ or $\tau = \tau(q, \tau_J, \dot{q}, \dot{\tau}_J, v)$. Indeed, the evaluation of the various derivatives of the dynamic model terms that are present in these expressions should be properly organized or customized in order to optimize computations.

Based on the resulting (11.47), the trajectory-tracking problem is solved by setting

$$\begin{aligned} v &= q_d^{[4]} + K_3 (q_d^{[3]} - q^{[3]}) + K_2 (\ddot{q}_d - \ddot{q}) \\ &\quad + K_1 (\dot{q}_d - \dot{q}) + K_0 (q_d - q), \end{aligned} \quad (11.50)$$

where it is assumed that the reference trajectory $q_d(t)$ is (at least) three times continuously differentiable (i.e., the fourth derivative $q_d^{[4]}$ exists), and the *diagonal* matrices K_0, \dots, K_3 have scalar elements $K_{\cdot,i}$ such that

$$s^4 + K_{3,i}s^3 + K_{2,i}s^2 + K_{1,i}s + K_{0,i}, \quad i = 1, \dots, N,$$

are Hurwitz polynomials. In view of the obtained decoupling, the trajectory error

$$e_i(t) = q_{d,i}(t) - q_i(t)$$

for the i -th link satisfies then

$$e_i^{[4]} + K_{3,i}e_i^{[3]} + K_{2,i}\ddot{e}_i + K_{1,i}\dot{e}_i + K_{0,i}e_i = 0;$$

yielding $e_i(t) \rightarrow 0$ in a global exponential way, for any initial state. A series of remarks are in order:

- When the initial state $(q(0), \theta(0), \dot{q}(0), \dot{\theta}(0))$ is matched with the reference trajectory and its first three derivatives at time $t=0$ (for this check, (11.48) and (11.49) are to be used), exact reproduction of the reference trajectory is achieved at all times.
- In the case of a discontinuity of the reference position trajectory, or of any of its first three derivatives, at a time $t^* \in [0, T]$, a trajectory error occurs at $t = t^*$ that will again decay to zero, independently for each link and with the prescribed exponential rate.
- The choice of the gains $K_{3,i}, \dots, K_{0,i}$ can be made by a pole placement technique (equivalent in this case to an eigenvalue assignment). Let $\lambda_1, \dots, \lambda_4$ be four poles with negative real parts, possibly given in complex pairs and/or coincident, specifying the desired transient of the trajectory error. These closed-loop poles will be assigned by the unique choice of real and positive gains

$$\begin{aligned} K_{3,i} &= -(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4), \\ K_{2,i} &= \lambda_1(\lambda_2 + \lambda_3 + \lambda_4) + \lambda_2(\lambda_3 + \lambda_4) + \lambda_3\lambda_4, \\ K_{1,i} &= -[\lambda_1\lambda_2(\lambda_3 + \lambda_4) + \lambda_3\lambda_4(\lambda_1 + \lambda_2)], \\ K_{0,i} &= \lambda_1\lambda_2\lambda_3\lambda_4. \end{aligned}$$

When the values of link and motor inertias are very different from each other, or when the joint stiffness is very large, the above fixed choice of gains has the drawback of generating too large control efforts. In those cases, a more tailored set of eigenvalues can be assigned scheduling their placement as a function of the physical data of robot inertias and joint stiffnesses.

- When compared to the *computed torque* method for rigid robots, the feedback linearization control

for trajectory tracking given by (11.46)–(11.50) requires the inversion of the inertia matrix $M(q)$ and the additional evaluation of derivatives of the inertia matrix and of other terms in the dynamic model.

- The feedback linearization approach can also be applied without any changes in the presence of viscous (or otherwise smooth) friction at the motor and link side. The inclusion of spring damping leads instead to a third-order decoupled differential relation between the auxiliary input v and q , leaving thus a N -dimensional unobservable dynamics in the closed-loop system, which is, however, still asymptotically stable. In this case, only input–output (and not full-state) linearization and decoupling is achieved.

We conclude with some considerations on exact linearization/decoupling by feedback for the general model (11.7) of robots with elastic joints. Unfortunately, due to the presence of the inertial coupling matrix $S(q)$ between links and rotors, the above control design can no longer be applied. Consider as an illustration the case of a constant S in (11.7), with the associated model simplifications. Solving for $\ddot{\theta}$ from the motor equations, $\ddot{\theta} = B^{-1}(\tau - \tau_J - S^T\ddot{q})$, and substituting into the link equations leads to

$$\begin{aligned} [M(q) - SB^{-1}S^T]\ddot{q} + n(q, \dot{q}) - (I + SB^{-1})\tau_J \\ = -SB^{-1}\tau. \end{aligned}$$

In this case, the input torque τ appears already in the expression for the link acceleration \ddot{q} . Using (11.6), the expression of the decoupling matrix is then

$$A(q) = -[M_L(q) + M_R(q)]^{-1}SB^{-1},$$

which is never full rank in view of the structure (11.5) of S . As a consequence, the necessary condition for obtaining (at least) input–output linearization and decoupling by static state feedback fails to hold.

However, by resorting to the use of a larger class of control laws, it is still possible to obtain an exact linearization and decoupling result. For this purpose, consider a *dynamic* state feedback controller of the form

$$\begin{aligned} \tau &= \alpha(q, \dot{q}, \theta, \dot{\theta}, \xi) + \beta(q, \dot{q}, \theta, \dot{\theta}, \xi)v, \\ \dot{\xi} &= \gamma(q, \dot{q}, \theta, \dot{\theta}, \xi) + \delta(q, \dot{q}, \theta, \dot{\theta}, \xi)v, \end{aligned} \quad (11.51)$$

where $\xi \in \mathbb{R}^p$ is the state of the dynamic compensator, α , β , γ , and δ are suitable nonlinear vector functions, and $v \in \mathbb{R}^N$ is (as before) an external input used for trajectory-tracking purposes. It is possible to show in general that a dynamic compensator (11.51) of order

at most $v = 2N(N-1)$ can be designed so as to yield a closed-loop system that is globally described by

$$\mathbf{q}^{[2(N+1)]} = \mathbf{v}, \quad (11.52)$$

in place of (11.47). Note the coincidence of this differential order with the one found for exact reproducibility of a desired trajectory $\mathbf{q}_d(t)$ in Sect. 11.1.2. The tracking problem is then solved by working on (11.52), with a direct generalization of the linear stabilization design in (11.50).

It is interesting to give a physical interpretation for this control result. The structural obstruction to input–output decoupling of the model (11.7) is related to the fact that the motion of a link attached to an elastic joint is affected *too soon* (at the second differential level) by torques originating at other elastic joints. This is due to the inertial couplings present between motors and links. The addition of dynamics (i.e., of integrators) in the controller slows down these low-energy paths and allows for the high-energy effects of the elastic torque at the local joint (a fourth-order differential path) to come into play. This dynamic balancing allows both input–output decoupling and exact linearization of the extended system (having the robot and the controller states).

Linear Control Design

The feedback linearization approach to trajectory tracking gives rise to a rather complex nonlinear control law. Its main advantage of globally enforcing a linear and decoupled behavior to the trajectory error dynamics should be traded-off with a control design that achieves only local stability around the reference trajectory, but is much simpler to implement (and may run at higher sampling rates).

For this, the inverse dynamics results of Sect. 11.1.2 can be used, assuming either the reduced or the complete robot model, with and without dissipative terms. Given a sufficiently smooth desired link trajectory $\mathbf{q}_d(t)$, we have seen that it is always possible to associate:

1. The nominal torque $\boldsymbol{\tau}_d(t)$ needed for its exact reproduction.
2. The reference evolution of all other state variables (e.g., $\boldsymbol{\theta}_d(t)$, as given by (11.13), or $\boldsymbol{\tau}_{J,d}(t)$).

These signals define a sort of steady-state (though, time-varying) operation for the system.

A simpler tracking controller combines a model-based feedforward term with a linear feedback term using the trajectory error. The linear feedback locally stabilizes the system around the reference state trajectory, whereas the feedforward torque is responsible for maintaining the robot along the desired motion as soon

as the error has vanished (see some examples on the tracking of square paths in [VIDEO 136](#)).

Using full-state feedback, two possible controllers of this kind are

$$\begin{aligned} \boldsymbol{\tau} = & \boldsymbol{\tau}_d + \mathbf{K}_{P,\theta}(\boldsymbol{\theta}_d - \boldsymbol{\theta}) + \mathbf{K}_{D,\theta}(\dot{\boldsymbol{\theta}}_d - \dot{\boldsymbol{\theta}}) \\ & + \mathbf{K}_{P,q}(\mathbf{q}_d - \mathbf{q}) + \mathbf{K}_{D,q}(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) \end{aligned} \quad (11.53)$$

and

$$\begin{aligned} \boldsymbol{\tau} = & \boldsymbol{\tau}_d + \mathbf{K}_{P,\theta}(\boldsymbol{\theta}_d - \boldsymbol{\theta}) + \mathbf{K}_{D,\theta}(\dot{\boldsymbol{\theta}}_d - \dot{\boldsymbol{\theta}}) \\ & + \mathbf{K}_{P,J}(\boldsymbol{\tau}_{J,d} - \boldsymbol{\tau}_J) + \mathbf{K}_{D,J}(\dot{\boldsymbol{\tau}}_{J,d} - \dot{\boldsymbol{\tau}}_J). \end{aligned} \quad (11.54)$$

These trajectory tracking schemes are the most common in the control practice for robots with elastic joints. In the absence of full-state measurements, they can be combined with an observer of the unmeasurable quantities. An even simpler realization is

$$\boldsymbol{\tau} = \boldsymbol{\tau}_d + \mathbf{K}_P(\boldsymbol{\theta}_d - \boldsymbol{\theta}) + \mathbf{K}_D(\dot{\boldsymbol{\theta}}_d - \dot{\boldsymbol{\theta}}), \quad (11.55)$$

which uses only motor measurements and relies on the results obtained for the regulation case.

The different gain matrices used in (11.53)–(11.55) have to be tuned using a linear approximation of the robot system. This approximation may be obtained at a fixed equilibrium point or around the actual reference trajectory, leading respectively to a linear time-invariant or to a linear time-varying system. While the existence of (possibly time-varying) stabilizing feedback matrices is guaranteed by the controllability of these linear approximations, the validity of the approach is only *local* in nature and the region of convergence will depend both on the given trajectory and on the robustness of the designed linear feedback.

It should be mentioned that such a control approach to trajectory tracking problems can be used also for robots with flexible links. Once the inverse dynamics problem has been solved (for the case of link flexibility, this typically results in a noncausal solution), a controller of the form (11.55) (or (11.53), with link deflection $\boldsymbol{\delta}$ and deflection rate $\dot{\boldsymbol{\delta}}$ replacing, respectively, \mathbf{q} and $\dot{\mathbf{q}}$), can be directly applied.

11.1.5 Further Reading

This section contains the main references for the part of this chapter on robots with joint flexibility. In addition, we point out to a larger bibliography for topics that have not been included here.

Early interest in problems arising from the presence of flexible transmissions in industrial robots dates back to [11.1, 2], with first experimental findings on the

GE P-50 arm. Relevant mechanical considerations involved in the design of robot arms and in the evaluation of their compliant elements can be found in [11.3].

One of the first studies on the inclusion of joint elasticity in the dynamic modeling of robot arms is due to [11.4]. The detailed analysis of the model structure presented in Sect. 11.1.1 comes from [11.5], with some updates from [11.6]. The simplifying assumption leading to the reduced model was introduced in [11.7]. The special case of motors mounted on the driven links is considered in [11.8]. The observation that joints with limited elasticity lead to a singularly perturbed dynamic model was first recognized in [11.9]. Symbolic manipulation programs for the automatic generation of dynamic models of robots with elastic joints were also developed very early [11.10].

The inverse dynamics computations in Sect. 11.1.2 can be traced back to [11.11, 12]. The use of programs such as Modelica for the numerical evaluation of inverse dynamics is highlighted in [11.6]. An efficient Newton–Euler inverse dynamics algorithm for robots with elastic joints has been proposed in [11.12].

The first specific control designs were based on decentralized linear controllers, see, e.g., [11.13] and [11.14], where a fourth-order dynamics local to each elastic joint was used. However, schemes with proved global convergence characteristics appeared only later.

In Sect. 11.1.3, the PD controller with constant gravity compensation is a contribution of [11.15]. This was also extended to the case of robots with flexible links in [11.16]. The first two versions of regulation control with online gravity compensation are due, respectively, to [11.17] and [11.18]. Both these control laws were extended to Cartesian compliance schemes in [11.19–21]. The PD-like controller (11.38), with perfect cancellation of gravity effects on link motion, is a result of [11.22]. A general regulation framework based on energy shaping has been proposed in [11.23]. In the absence of any information on gravity, a proportional–integral–derivative (PID) regulator with semiglobal stability properties has been presented in [11.24], while a global learning scheme was proposed in [11.25].

The presentation of a full-state feedback design for regulation (and tracking) follows the idea used in [11.26]. Special interest has been devoted over the years to joint torque feedback, from the placement of torque sensors on transmission shafts [11.27] or within harmonic drives [11.28] to their use for achieving robust control performance [11.29].

The fact that the reduced model of robots with elastic joints can always be feedback linearized via static state feedback was shown for the first time in [11.7]. A previous similar result for a specific robot kinematics

can be found in [11.30]. The discrete-time implementation of the feedback linearization approach has been studied in [11.31], while its robustness properties were analyzed in [11.32]. Feedback linearization and input–output decoupling were also considered for the case of viscoelastic joints in [11.33], and for robots with joints of mixed type, some rigid and some elastic, in [11.34]. The same idea of inversion control, leading to input–output decoupling and linearization, has also been successfully applied to the tracking problem of joint-level trajectories in robots with flexible links [11.35].

For the general model of robots with elastic joints, the use of dynamic state feedback was first proposed in [11.36]. A comparative study of the errors induced by neglecting the motor–link inertia couplings (thus, for robots that are not linearizable by static state feedback) was carried out in [11.37]. The general algorithm for constructing the dynamic linearizing feedback is presented in [11.38, 39].

The benefit of combining a stabilizing feedback with a feedforward command in robots with flexible joints was experimentally shown for the first time in [11.39] (see also the  VIDEO 770) and then formalized in [11.11].

Other control design methodologies available for trajectory tracking, which were not discussed in Sect. 11.1.4, are based on singular perturbation, backstepping, or passivity. Nonlinear controllers based on the two-time scale separation property were proposed by [11.40] and [11.41]. These corrective controllers are an outcome of the singular perturbation model form and should be preferred in the case of very stiff joints, as they do not generate high-gain laws in the limit. Backstepping is based on the idea of considering the joint elastic torque [11.42] or the motor position [11.43] as an intermediate fictitious input to be used to control the link equations, and then to design the actual torque input in the motor equations so as to follow the reference behavior for the previous intermediate input. The main advantage is that this design may be easier to be transformed into an adaptive version. Adaptive control results for robots with elastic joints include the high-gain (approximate) schemes [11.44] and [11.45], as well as the global (but very complex) solution obtained in [11.46], both analyzed using only the reduced dynamic model. Moreover, robust control schemes have been proposed in [11.47], based on sliding mode techniques, and in [11.48–52], using iterative learning on repetitive tasks.

As for optimal control results, the intrinsic fourth-order dynamics associated to flexible joints has barred so far the derivation of analytical or numerically efficient results. Finding the time-optimal velocity profile

on a constrained geometric path is a solved problem in the rigid case, but only an approximate solution is available for robots with elastic joints [11.49]. A useful generalization from the rigid to the elastic case is the dynamic trajectory scaling algorithm of [11.50], which provides a closed-form expression to the uniform time scaling that recovers feasibility of commanded torques w.r.t. their bounds. Selected optimal control problems for single viscoelastic joints, involving either the maximization of stored potential energy or the minimization of rest-to-rest motion time, have been tackled and solved in [11.51] and [11.52], respectively.

Different state observers have been presented, starting from an approximate one [11.53] up to the exact ones in [11.5, 54], in which a tracking controller based on the estimated state was also tested. In all cases, link position or link position and velocity measurements are

assumed. On the other hand, the use of motor position and link acceleration has been shown to be a feasible alternative for robust state reconstruction [11.55].

Finally, the force control problem in constrained tasks for robots with elastic joints has been tackled following a singular perturbation technique [11.56, 57], an inverse dynamics approach [11.58], or an adaptive strategy [11.59].

A unified passivity-based approach has been presented in [11.60], where an inner torque feedback loop is incorporated for shaping (viz., reducing) the motor inertia. This enables approximate gravity compensation (as done in Sect. 11.1.3), as well as to assign a desired Cartesian stiffness relation for the link positions, mimicking the impedance control of the rigid case for handling interactions and contacts with the environment.

11.2 Robots with Flexible Links

Arm flexibility is a dynamic behavior in which kinetic energy interacts with elastic potential energy. Kinetic energy is stored in moving inertia, and potential energy is stored in compliant members. Flexible links provide both the inertia and compliance distributed throughout the member. Flexibility manifests itself as mechanical oscillations and static deflections, greatly complicating the motion control of a mechanical arm. If the time to settle the oscillations is significant relative to the cycle time of the overall task, flexibility will be a major consideration in the arm design.

11.2.1 Design Issues

We will deal with these issues in a modular way, separating link flexibility and joint flexibility. The first topic of link flexibility deals with the inherent spatial distribution of compliance and inertia, perhaps with both effects existing in the same element of material. The links of a manipulator arm can usually be stiffened by adding structural mass or by improving the material properties or distribution over the links. At some points, the links may be treated as rigid. The designer must realize that an arm with heavy rigid links and flexible joints may be more flexible dynamically than a lighter arm with more link flexibility and less inertia. The consequences are predicted by the natural frequency of the first flexible mode of motion, with the joint actuators locked, which can be approximated by

$$\omega_1 = \sqrt{\frac{k_{\text{eff}}}{I_{\text{eff}}}}, \quad (11.56)$$

where k_{eff} is the effective spring constant and I_{eff} is the effective inertia. For the elastic joint case, k_{eff} and I_{eff} are directly available from the elastic joint parameters and mass properties of the arm. The *effective* values applicable to a simple beam in bending, for example, would result from boundary conditions that are clamped at one end and free at the other and would be selected to yield a good approximation to the natural frequency. This natural frequency is readily available from handbooks on vibration in this case as $\omega_1 = 3.52 \sqrt{EI/ml^4}$. (The variables are used in (11.57) and (11.58) and defined below.) More complex geometries can be evaluated by various means, including the transfer matrix method discussed in Sect. 11.2.2 on modeling. The arm should be considered flexible when this frequency is low enough to interfere with the design of controllers based on rigid assumptions. The common PD control of a single joint on a flexible link can only achieve adequate damping of a closed-loop design when the magnitude of the closed loop poles is less than about 1/3 of ω_1 [11.61].

A distillation of the key aspects of the mechanics of materials is now in order. In some cases static compliance effects represent a member sufficiently, whereas in other cases the true distributed nature of compliance and mass and its dynamics must be modeled. A long structural member with forces f and moments M perpendicular to its long axis is subject to bending. Static bending relates the moment at the axial location x to the displacement w

$$M(x) = EI(x) \frac{\partial^2 w}{\partial x^2}, \quad (11.57)$$

where E is the elastic modulus of the material, and $I(x)$ is the area moment of inertia about the neutral axis of the cross section. The deflection at any point is obtained by integrating this equation from a reference point to a desired point, such as the end of the link.

This is a description of compliance that can be used when mass is isolated from elasticity. If mass is distributed throughout the beam with material mass density per unit volume ρ , the time t must be incorporated so that

$$m(x) \frac{\partial^2 w(x, t)}{\partial t^2} + \frac{\partial^2}{\partial x^2} \left(EI(x) \frac{\partial^2 w(x, t)}{\partial x^2} \right) = 0. \quad (11.58)$$

Here $m(x)$ is the mass density per unit length, incorporating the material properties and the cross-sectional area at x . Assumptions implicit in this equation, which is called the Bernoulli–Euler equation, include the minimal impact of shear distortion and rotational inertia of the cross section of the beam, which is valid for long beams. The Timoshenko beam model relaxes these assumptions but is not included here.

Torsional deflection of an angle θ results if a twisting moment T about the long beam axis occurs, such that, in the static case

$$\theta = \frac{Tl}{JG} = \alpha_{\theta T} T, \quad (11.59)$$

where G is the shear modulus of the material, and J is the polar area moment of inertia about the neutral axis of the beam. Again, the addition of a distributed mass and considering the dynamics produces a partial differential equation with independent variables in space and time

$$\mu(x) \frac{\partial^2 \theta}{\partial t^2} = GJ \frac{\partial^2 \theta}{\partial x^2}, \quad (11.60)$$

where $\mu(x)$ is the rotary mass moment of inertia per unit length of the shaft. While (11.60) is potentially appropriate for links, the smaller rotational mass moment of inertia of a long slender shaft relative to the links it drives results in the static compliance effects of torsion given by (11.59) being of most importance.

Tension and compression effects should also be acknowledged, although they tend to be the least significant. Here deflection δ in the x -direction (the long axis of the member) results from axial force F_a and is calculated as $\delta = \frac{F_a L}{AE}$

$$\delta = \frac{F_a L}{AE} = \alpha_{\delta F} F_a, \quad (11.61)$$

where L is the element length and A is its cross sectional area. In the dynamic case, with mass density ρ and displacement ξ , the axial motion is described by

$$\rho \frac{\partial^2 \xi}{\partial t^2} = E \frac{\partial^2 \xi}{\partial x^2}. \quad (11.62)$$

Note that these effects are special cases of the more general elastic behavior of a member subject to acceleration and external loading, specialized to the member with one long axis. The same general phenomena apply to joint structures (e.g., bearings and couplings) and drive-train components (e.g., gears and cables). The functional constraints on the structural design of these members may be more severe and limit the designer's ability to make them more rigid by adding more material. Under this constraint, the combined compliance of the flexible joint design and the rigidized link design results in inferior performance of the combination. A less rigid link with less inertia will raise the lowest natural frequency. Thus the design of the link and the joint must be coordinated.

Flexibility is only one of several link design constraints. Static compliance is obviously another based on the above discussion. Buckling and strength are two more considerations that constrain some of the same design parameters. While it has been shown that flexibility is a dominant constraint for typical arm design regimes [11.62], a simple optimization of bending stiffness of a beam with a tubular geometry illustrates the fallacy of ignoring buckling. If the radius of the tube is varied to maximize bending stiffness with constrained total mass, the radius increases without bound, producing a thin shell of infinitesimal thickness and infinite radius that lacks robustness. The true constraint becomes local buckling of the tube under slight perturbations of the applied load. A thin metal can illustrates this behavior as it crushes. Strength is another applicable constraint. Various materials differ in their strength, typically represented by their elastic limit or endurance limit on the stress at a point in the member. A sufficiently stiff member may fail due to stress, particularly at points of stress concentration.

In this presentation of options to overcome flexibility, and link flexibility in particular, radically different operational and design strategies should be recognized even though they are not the core of the treatment. The elastic modulus relates stress to strain, but physically the strain rate is sometimes a relevant term, providing structural damping to augment the joint or control-based damping. Composite materials have substantially more damping inherent in their behavior. Damping can be enhanced with passive damping treatments, with constrained layer damping having particularly pronounced effects [11.63]. Smart materials can also be

configured to enhance damping [11.64]. An operational strategy known as *bracing* can be combined with redundant actuation to achieve a large workspace for a flexible arm that provides gross motion and a smaller precision workspace after docking the large arm with a stationary structure, as described in [11.65].

The implication above is that flexibility was always due to the moving parts of the arm. However, the arm base itself may be a source of significant flexibility. If the base is stationary, the analysis may be almost identical to that of the flexible links of an arm. However, if the arm is mounted on a vehicle, tires or tracks may be the source of flexibility and empirical evaluation of these new elements might be the best solution. The vehicle could be a boat, aircraft, or space vehicle. Here there is no elastic connection to an inertial reference frame and some fundamental changes in approach will be needed. These changes are not unexplored and in some cases are simple extensions of the following approaches.

11.2.2 Modeling of Flexible Link Arms

Mathematical models of link flexibility trade accuracy for ease of use. It is therefore key to determine the effects that are important to represent accurately. The techniques presented here will assume linear elasticity with light damping. Rotational motions must be of modest angular rate so that centrifugal stiffening can be ignored. Small deflections will generally be assumed. These are reasonable assumptions for most robotic devices, but can be violated in more exotic applications, requiring reevaluation of the assumptions and more tortuous modeling approaches.

Four model types will be examined:

1. Lumped-element models having compliance or inertia but not both in a given member.
2. Finite-element models, which will be only briefly addressed.
3. Assumed mode models which readily include nonlinear dynamic behavior.
4. Transfer matrix models that incorporate the true distributed intermingling of compliance and inertia and consequently the infinite-dimensional nature of flexible link arms.

With the limited space available here, the discussion will be preliminary but should enable the reader to pursue one or more alternatives knowledgeably.

For lumped elements, one may build on the rigid kinematics presented in the section on fundamentals of kinematics (Chap. 2) that establishes rigid transformation matrices \mathbf{A}_i . The 4×4 homogenous transformations that describe position can be used to describe deflection

as well. Assuming small motions and static behavior (or negligible member mass), the transformation produced by elastic bending, torsion, and compression is

$$\mathbf{E}_i = \begin{pmatrix} 1 & -\alpha_{\theta Fi} F_{Yi}^i - \alpha_{\theta Mi} M_{Zi}^i & 0 & 0 \\ \alpha_{\theta Fi} F_{Yi}^i + \alpha_{\theta Mi} M_{Zi}^i & 1 & 0 & 0 \\ \alpha_{\theta Fi} F_{Zi}^i - \alpha_{\theta Mi} M_{Yi}^i & \alpha_{Ti} M_{Xi}^i & 0 & 0 \\ 0 & 0 & -\alpha_{\theta Fi} F_{Zi}^i + \alpha_{\theta Mi} M_{Yi}^i & \alpha_{Ci} F_{Xi}^i \\ -\alpha_{\theta Fi} F_{Zi}^i + \alpha_{\theta Mi} M_{Yi}^i & \alpha_{XFi} F_{Yi}^i + \alpha_{XMi} M_{Zi}^i & \alpha_{XFi} F_{Zi}^i + \alpha_{XMi} M_{Yi}^i & 1 \\ 0 & 1 & 0 & 0 \end{pmatrix}, \quad (11.63)$$

where

α_{Ci} = coefficient in compression, displacement/force ,

α_{Ti} = coefficient in torsion, angle/moment ,

$\alpha_{\theta Fi}$ = coefficient in bending, angle/force ,

$\alpha_{\theta Mi}$ = coefficient in bending, angle/moment ,

α_{XFi} = coefficient in bending, displacement/force ,

α_{XMi} = coefficient in bending, displacement/moment ,

F_{Xi}^j = the force at the end of link i in the X direction of coordinate frame j ,

F_{Yi}^j = the force at the end of link i in the Y direction of coordinate frame j ,

F_{Zi}^j = the force at the end of link i in the Z direction of coordinate frame j ,

M_{Xi}^j = the moment at the end of link i in the X direction of coordinate frame j ,

M_{Yi}^j = the moment at the end of link i in the Y direction of coordinate frame j ,

M_{Zi}^j = the moment at the end of link i in the Z direction of coordinate frame j .

The listed coefficients depend on the construction of the element and are readily found for a slender beam from simple strength of materials. In other cases, a finite-element model or empirical measurements may be more readily used.

Alternating transformations for the undeformed and deformed aspects of N members (links or joints) produces the position vector of the end of arm (EOA)

$$\mathbf{p}^0 = (\mathbf{A}_1 \mathbf{E}_1 \mathbf{A}_2 \mathbf{E}_2 \dots \mathbf{A}_i \mathbf{E}_i \mathbf{A}_{i+1} \mathbf{E}_{i+1} \dots \mathbf{A}_N \mathbf{E}_N) \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \quad (11.64)$$

If the massless elements connect rigid lumped masses, a linear spatial model is readily obtained, as described in [11.66]. Servo-controlled joints can also be inserted into this model. This analysis proceeds by examining the deflection of the elastic members produced by joint motion and the resulting forces and moments on the rigid inertias at the ends of the chain of links. The reference concentrates on the special case of only two inertias at each end of the chain but the technique is easily extended to inertias in the middle of the chain as well. The results are six linear second-order equations for each inertia and one first-order equation for each joint.

If the compliance and inertia properties are both to be treated as distributed throughout the same element, the partial differential equations (PDEs) introduced in the previous section for bending, torsion, and compression must be employed. Still insisting on a linear treatment, the general solution of these equations can be found in terms of each element with adjoining elements, i.e., the boundary conditions on the PDE. The convenient approach of Laplace transformation of these linear equations into the frequency domain, followed by factoring out the boundary conditions into a matrix–vector product, results in a technique known as the transfer matrix method (TMM) [11.67]. This method has been applied productively to general elastomechanics problems as well as specifically to flexible arms [11.68].

The transfer matrix relates variables at two stations along the arm with the number of variables depending on the model complexity. For the planar bending, deflection of the beam is shown in Fig. 11.9

$$\mathbf{z}_1 = \begin{pmatrix} -W \\ \psi \\ M \\ V \end{pmatrix}_1 = \begin{pmatrix} \text{displacement} \\ \text{angle} \\ \text{moment} \\ \text{shear force} \end{pmatrix}_{\text{at station 1}}, \quad \mathbf{z}_0 = \mathbf{T}\mathbf{z}_1, \quad (11.65)$$

where T is the appropriate element transfer matrix.

If the element is a simple rotary spring with constant k and a damper with constant b , then the angle of rotation θ is related to the moment by a differential

Fig. 11.9 State vector for the bending transfer matrix

equation with the following Laplace-domain representation

$$M = -L(k\theta + b\dot{\theta}) \Rightarrow k\Theta(s) + bs\Theta(s) = M_0 = M_1,$$

$$W_0 = W_1,$$

$$V_0 = V_1,$$

$$\Psi_0 = \Psi_1 - \Theta(s) = \Psi_1 - \frac{1}{k + bs}M_1.$$

Note that the only variable changed across the element is the angle related to the moment. The transfer matrix representation conventionally uses zero initial conditions and converts to the Fourier representation with $s = i\omega$. This leads to the transfer function

$$\mathbf{T} = \mathbf{C}(i\omega) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & \frac{1}{k + b(i\omega)} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

which has the same form of the joint controller as shown in (11.69).

The beam model is much more complex, and the Euler–Bernoulli model gives

$$\mathbf{B} = \begin{pmatrix} c_0 & lc_1 & ac_2 & alc_3 \\ \frac{\beta^4 c_3}{l} & c_0 & \frac{ac_1}{l} & ac_2 \\ \frac{\beta^4 c_2}{a} & \frac{\beta^4 lc_3}{a} & c_0 & lc_1 \\ \frac{\beta^4 c_1}{al} & \frac{\beta^4 c_2}{a} & \frac{\beta^4 c_3}{l} & c_0 \end{pmatrix}, \quad (11.66)$$

where

$$\begin{aligned} \beta^4 &= \omega^2 l^4 \mu / (EI); \quad a = l^2 / (EI), \\ c_0 &= (\cosh \beta + \cos \beta) / 2, \\ c_1 &= (\sinh \beta + \sin \beta) / (2\beta), \\ c_2 &= (\cosh \beta - \cos \beta) / (2\beta^2), \\ c_3 &= (\sinh \beta - \sin \beta) / (2\beta^3), \\ \mu &= \text{density/unit length}, \\ \omega &= \text{circular frequency of vibration}, \\ E &= \text{elastic modulus}, \\ I &= \text{cross-sectional area moment of inertia}. \end{aligned}$$

The spatial variable has been transformed to the spatial Laplace variable but no longer appears explicitly. The Laplace time variable remains and is designated by s or by the frequency variable $\omega = -is$, where $i = \sqrt{-1}$.

The other transfer matrices needed for a simple planar model are as follows.

For a rotation in the plane of angle φ

$$\mathbf{A} = \begin{pmatrix} \frac{1}{\cos \varphi} & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ m_s \omega^2 \sin \varphi \tan \varphi & 0 & 0 & \cos \varphi \end{pmatrix}, \quad (11.67)$$

where m_s is the sum of all outboard masses from the angle to the end of the arm. This is an approximation resulting from ignoring compression elasticity. These elements appear as an additional mass to the extent they are translated with beam compression.

For a rigid mass, simply applying Newton's laws and collecting term yields

$$\mathbf{R} = \begin{pmatrix} 1 & l & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -\frac{m\omega^2 l}{2} & I_m \omega^2 - \frac{m\omega^2 l^2}{2} & 1 & l \\ m\omega^2 & -\frac{m\omega^2 l}{2} & 0 & 1 \end{pmatrix}, \quad (11.68)$$

where m is the mass of the body, I_m is the mass moment of inertia about an axis through the center of mass and perpendicular to the plane of the arm, l is the length of the mass (the distance between the points of attachment at stations i and $i+1$), and $l/2$ is the distance to the center of mass from station i .

For a controlled joint with the controller transfer function (joint torque/joint angle) = $k(i\omega)$

$$\mathbf{C} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & \frac{1}{k(i\omega)} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (11.69)$$

When combined to represent the planar arm with two joints as shown in Fig. 11.10, this analysis yields a composite transfer matrix that relates the four state variables at the two ends of the arm. Further analysis results from imposing the known boundary conditions at these ends.

The transfer matrix representation of an arm presented in [11.69] and pictured in Fig. 11.10 is shown in (11.70).

$$\begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_0 = \mathbf{R}_1 \mathbf{B}_2 \mathbf{R}_3 \mathbf{A}_4 \mathbf{C}_5 \mathbf{B}_6 \mathbf{R}_7 \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_7. \quad (11.70)$$

In the example, the left end is pinned and the right end is free, yielding

$$\mathbf{z}_0 = \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_0 = \begin{pmatrix} u_{11} & u_{12} & u_{13} & u_{14} \\ u_{21} & u_{22} & u_{23} & u_{24} \\ u_{31} & u_{32} & u_{33} & u_{34} \\ u_{41} & u_{42} & u_{43} & u_{44} \end{pmatrix} \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_7, \quad (11.71)$$

$$\begin{pmatrix} u_{11} & u_{12} \\ u_{31} & u_{32} \end{pmatrix} \begin{pmatrix} -W \\ \Psi \end{pmatrix}_7 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

The determinant of the 2×2 matrix must be zero when ω is a natural frequency, or a system eigenvalue if it is complex. This can be found by a numerical search. Evaluating variables (position, angle, shear, and moment) along the length of the arm with the eigenvalues used for the values of ω yields the eigenfunctions. If boundary conditions are not zero but known for given frequencies, the frequency response of the system can be obtained. Hence Bode plots are readily obtained for boundary condition forcing. Interior forcing can be handled using an extended state vector as described in [11.67], which was applied to arms in [11.61] and most recently updated with modern programming techniques in [11.68]. Inverse fast Fourier transform (FFT) will produce a time-domain response from the frequency response.

The creation of a state-space model in the time domain is attractive because it enables the use of powerful state-space design techniques and is compatible with the nonlinear behavior of arms undergoing large motion and experiencing centrifugal and Coriolis forces. The assumed modes method allows such a model to be constructed efficiently. The presentation here follows the early introduction of a recursive manner to calculate these equations introduced in [11.70]. The flexible kinematics of the links must be expressed as a sum of basis functions also known as assumed modes (shapes) $\varphi_i(x)$ with time-variable amplitudes $\delta_i(t)$

$$w(x, t) = \sum_{i=1}^{\infty} \delta_i(t) \varphi_i(x). \quad (11.72)$$

Fig. 11.10 Transfer matrix representation of an arm

The amplitudes and their derivatives become the states of the model. Compatible joint angle variables and their derivatives are also included as the rigid state variables. Joint angles tangent to the ends of the flexible links are compatible with mode shapes based on the clamped boundary conditions at one end and free boundary conditions at the other. This choice is generally chosen for simulation and the rigid coordinates are directly measured by standard joint angle transducers. If rigid coordinates are angles measured between lines connecting successive joint axes, the end of arm is known in terms of rigid coordinates alone and pinned–pinned boundary conditions are consistent. This produces advantages for inverse dynamics calculations as seen shortly.

The flexible and rigid kinematics combined describes the position and velocity of every point on the arm and can be used to express the kinetic energy \mathcal{T} and the potential energy \mathcal{V} . These expressions are used in the conservative form of Lagrange's equation

$$\frac{d}{dt} \frac{\partial \mathcal{T}}{\partial \dot{q}_i} - \frac{\partial \mathcal{T}}{\partial q_i} + \frac{\partial \mathcal{V}}{\partial q_i} = F_i, \quad (11.73)$$

where F_i is the force that does work as q_i is varied.

The kinematics of the deflection are again described by 4×4 transformation matrices, but this time the assumed mode shapes j are summed to give the position of link i

$$\mathbf{h}_i^j(\eta) = \begin{pmatrix} \eta \\ 0 \\ 0 \\ 1 \end{pmatrix} + \sum_{j=i}^{m_i} \delta_{ij} \begin{pmatrix} x_{ij}(\eta) \\ y_{ij}(\eta) \\ z_{ij}(\eta) \\ 0 \end{pmatrix}, \quad (11.74)$$

where x_{ij} , y_{ij} , and z_{ij} are the x_i , y_i , and z_i displacement components of mode j of link i 's deflection, respectively, δ_{ij} is the time-varying amplitude of mode j of link i , and m_i is the number of modes used to describe the deflection of link i

$$\mathbf{E}_i = \left(\mathbf{H}_i + \sum_{j=i}^{m_i} \delta_{ij} \mathbf{M}_{ij} \right), \quad (11.75)$$

where

$$\mathbf{H}_i = \begin{pmatrix} 1 & 0 & 0 & l_i \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (11.76)$$

and

$$\mathbf{M}_{ij} = \begin{pmatrix} 0 & -\theta_{zij} & \theta_{yij} & x_{ij} \\ \theta_{zij} & 0 & -\theta_{xij} & y_{ij} \\ -\theta_{yij} & \theta_{xij} & 0 & z_{ij} \\ 0 & 0 & 0 & 0 \end{pmatrix}. \quad (11.77)$$

This description is used in the formation of the potential and kinetic energy contributions of each element of mass. The integral over the link accumulates the total energy for that link and the sum over all links gives the energy of the arm system. Interchanging the order of integration and summation allows key invariant parameters to be identified, such as the *modal mass* that multiplies the second derivative of modal amplitude and the *modal stiffness* that multiplies the amplitude itself. The intermediate steps are aimed at the evaluation of Lagrange's equations, which separate into derivatives related to the rigid variables and the flexible variables. If the rigid variables θ are the joint variables, two groups of equations result

$$1. \quad \frac{d}{dt} \left(\frac{\partial \mathcal{T}}{\partial \dot{\theta}_j} \right) - \frac{\partial \mathcal{T}}{\partial \theta_j} + \frac{\partial \mathcal{V}_e}{\partial \theta_j} + \frac{\partial \mathcal{V}_g}{\partial \theta_j} = F_j \quad (11.78)$$

$$2. \quad \frac{d}{dt} \left(\frac{\partial \mathcal{T}}{\partial \dot{\delta}_{jf}} \right) - \frac{\partial \mathcal{T}}{\partial \delta_{jf}} + \frac{\partial \mathcal{V}_e}{\partial \delta_{jf}} + \frac{\partial \mathcal{V}_g}{\partial \delta_{jf}} = 0, \quad (11.79)$$

where the subscript e indicates elasticity, subscript g indicates gravity, and δ indicates the amplitude of a mode shape.

The simulation form of the equations is achieved by grouping all second derivatives of the rigid and flexible coordinates, which yields

$$\begin{pmatrix} \mathbf{M}_{rr}(\mathbf{q}) & \mathbf{M}_{rf}(\mathbf{q}) \\ \mathbf{M}_{fr}(\mathbf{q}) & \mathbf{M}_{ff}(\mathbf{q}) \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{\delta} \end{pmatrix} = - \begin{pmatrix} 0 & 0 \\ 0 & \mathbf{K}_s \end{pmatrix} \begin{pmatrix} \theta \\ \delta \end{pmatrix} + \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{G}(\mathbf{q}) + \mathbf{R}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{Q}), \quad (11.80)$$

where θ is a vector of rigid coordinates, usually the joint variables, δ is the vector of flexible coordinates, $\mathbf{q} = [\theta^T \delta^T]^T$, \mathbf{M}_{ij} is the *mass* matrix for rigid and flexible coordinates corresponding to the rigid ($i, j = r$) or flexible ($i, j = f$) coordinates and equations, $\mathbf{N}(\mathbf{q}, \dot{\mathbf{q}})$ contains the nonlinear Coriolis and centrifugal terms, $\mathbf{G}(\mathbf{q})$ captures gravity effects, \mathbf{Q} represents the externally applied forces, and \mathbf{R} captures the effect of external forces and all other nonconservative forces including friction.

On the other hand, the inverse dynamics form of the equations is (assuming negligible friction)

$$\mathbf{Q} = \begin{pmatrix} \mathbf{M}_{rr}(\mathbf{q}) & \mathbf{M}_{rf}(\mathbf{q}) \\ \mathbf{M}_{fr}(\mathbf{q}) & \mathbf{M}_{ff}(\mathbf{q}) \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{\delta} \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & \mathbf{K}_s \end{pmatrix} \begin{pmatrix} \theta \\ \delta \end{pmatrix} - \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) - \mathbf{G}(\mathbf{q}). \quad (11.81)$$

In general, Q is dependent on the vector T of motor torques or forces at the joints, and the distribution of these effects is such that

$$Q = \begin{pmatrix} B_r \\ B_f \end{pmatrix} T, \quad (11.82)$$

where T has the same dimensionality as q_r . By rearranging the inverse dynamics equation, we obtain

$$\begin{pmatrix} B_r & -M_{rf} \\ B_f & -M_{ff} \end{pmatrix} \begin{pmatrix} T \\ \ddot{\delta} \end{pmatrix} = \begin{pmatrix} M_{rr} \\ M_{rf} \end{pmatrix} \ddot{\theta} + N(q, \dot{q}) + G(q), \quad (11.83)$$

which is arranged with a vector of unknowns on the left-hand side of the equation and the prespecified rigid and solvable flexible coordinates on the right. This is at least approximately true, with the caveat that the nonlinear and gravity terms have a weak influence on the immediate flexible coordinates, which are not simultaneously known but which can be estimated for the next time step.

One consequence of the distributed flexibility is non-minimum-phase behavior. This can occur for other cases where the excitation is separated from the output point by mass and flexibility, a condition known as non-collocation. These systems are characterized by a step response in which the initial movement is opposite in sign from the final movement. This is simply characterized for linear systems as a transfer function zero in the right half-plane. As will be shown in the section on Command Generation, it may be possible to overcome this problem by redefining the output.

11.2.3 Control

Appropriate reaction to flexible dynamics requires appropriate sensors. While a Kalman filter can theoretically observe flexible link states from joint measurements, it is based on back driving the joint from the various modes of flexible dynamics. More reliable indications of flexibility include strain gauges, accelerometers, and optical sensors.

Sensors for Flexibility Control

The strain of a beam element is a direct indication of curvature, which is the second spatial derivative of beam deflection, as indicated in (11.57). Modern semiconductor strain gauges have high gauge factors producing a good signal-to-noise ratio. The second spatial derivative relationship means that a slight change in location can result in a large change in the reading, but once affixed to the arm this is not a problem. More of a problem is the relatively short lifetime of a strain gauge subject to wear and tear if not carefully protected.

By suitably placing strain gauges, good measurements of multiple assumed modes are possible.

Optical measurement of deflection can be very versatile but is subject to interference between a target measurement point and the sensor, particularly if the sensor is stationary. If the sensor is mounted on the link, this difficulty is reduced but optical measurements are then usually a complex combination of the rotation of the optical axis of the sensor and the deflection of the target. Machine vision senses a wide field of view but typically with less precision. Multiple points can be detected, which is attractive in measuring multiple modes. Machine vision requires considerable processing and, even for enhanced targets or retroreflective fiducials, sample rates can be slow relative to some modes of control interest.

Accelerometers are attractive transducers in that they do not require explicit grounding to a fixed frame. Microelectromechanical systems (MEMS) accelerometers provide the required low-frequency sensitivity and are very inexpensive. However, they are subject to orientation in a gravity field, which must be compensated for by knowing the orientation of the sensor. If one is interested in position, accelerometers require two integrations and are consequently subject to drift in position measurement. Consequently, the combined use of sensors is appealing. For example, vision sensors, which are relatively slow but give direct position information for the end of a flexible member, can be combined with accelerometers, which give information about the same point at high sample rates but with noise and drift problems. The two sensor readings can be combined with a Kalman filter or other fusion scheme.

Issues Related to Model Order

Realizing that the theoretical order of a flexible arm is infinite, one should be prepared to deal with certain issues related to model order. The first of these is possible aliasing problems arising from finite sampling rates. Antialiasing filters should be employed, and even more effective is the use of analog damping by materials, damping treatments, or the back electromotive force (emf) of actuators to provide an inherent damping of the system under digital control. A more subtle problem is that of measurement and control spill over.

Control of Special Configurations: Macro/Micro Redundancy

Several special configurations have been proposed to enable improved controlled performance of flexible link arms. The problem with noncollocation noted above is a case in point. In some cases, a large range of motion and high accuracy cannot be achieved with a single set of actuators. Redundant degrees of freedom can then

be employed with the macro degrees of freedom that provide large range of motion but with inherent lack of precision or accuracy. Vibrations are particularly difficult to eliminate with a long arm, and construction accuracy and even thermal drift can exceed the tolerance limits. If the gross motion is completed quickly, residual vibrations may remain and be very lightly damped. Actuators constructed for gross motions of large axes do not have the bandwidth capabilities to damp these vibrations actively, but small motion axes typically do. This has been illustrated in several instances for long-reach manipulators when exploring nuclear waste cleanup solutions [11.71–74]. Using the inertial forces generated at the end of the arm also has the advantage of creating forces collocated with the measurements being used for control, assuming the base of the micro arm is at the end of the macro arm and the location of sensors. *Book and Loper* [11.73] and *George and Book* [11.75] have shown that this control is possible based on accelerometers in multiple degrees of freedom. It is also possible to excite undesired modes which have not been accounted for. If the full six degrees of freedom are used it is possible to argue stability based on a simple passive analogy. Generating prescribed forces at the base of an articulated micromanipulator is a challenging task, requiring the solution of a new type of inverse dynamics problem, which solves for motions or joint torques to produce the prescribed base forces and moments.

Command Generation for Flexible Link Arms via Command Shaping

The trajectory undertaken by a flexible arm can dramatically affect the consequences of flexibility. Purely

Fig. 11.11 Impulse response of a shaper and the effect on a vibratory system. Time is normalized by the intersample time T_s and T_d , chosen such that $\Delta = T_d/T_s$ is an integer

open-loop anticipation of the flexible dynamics has been used to create motion profiles wherein the motion cancels the incipient oscillation that had been created by earlier motions. This strategy is referred to as command shaping. A more complicated strategy to implement is a true inverse-dynamics-based trajectory wherein the rigid and flexible states are all orchestrated to arrive at the desired point in state space, typically at a static equilibrium. The high order of the flexible model is further complicated by the non-minimum-phase nature of the noncollocated system and noncausal inverse is necessary to produce a physically realizable trajectory (VIDEO 778).

Time delay command shaping is a variation of the deadbeat control introduced by [11.76, 77]. It can be couched in terms of a finite impulse response filter with a simple impulse response as depicted in Fig. 11.11 with a single input impulse producing a small number (typically two to four) of output impulses with appropriate time spacing and amplitudes. Extensions by *Singer and Seering* [11.78] and *Singhose et al.* [11.79] have produced more robust varieties under the trademark Input Shaping. The robustness is enhanced by using more output impulses and appropriate selection of the impulse spacing. The optimal arbitrary time-delay (OAT) filter [11.80, 81] reduces this selection to a simple formula for linear vibrations that depends on the natural frequency and damping ratio of those modes to be eliminated from the response. The simplicity of implementation is illustrated in Fig. 11.12, where the relationships between the filter parameters and the mode parameters are

$$\begin{aligned}
 \text{coefficient 1} &= \frac{1}{M} \\
 \text{coefficient 2} &= \frac{-(2 \cos(\omega_d T_d) e^{-\zeta \omega_n T_d})}{M} \\
 \text{coefficient 3} &= \frac{e^{-2\zeta \omega_n T_d}}{M} \\
 M &= 1 - 2 \cos(\omega_d T_d) e^{-\zeta \omega_n T_d} + e^{-2\zeta \omega_n T_d} \\
 \omega_d &= \omega_n \sqrt{1 - \zeta^2} = \text{damped natural frequency} \\
 \omega_n &= \text{undamped natural frequency} \\
 \zeta &= \text{damping ratio} \\
 T_d &= \text{time delay selected, an integer number of samples.}
 \end{aligned}
 \tag{11.84}$$

Note that the formulation here is oriented toward digital systems with fixed sampling intervals such that the time delay of the filter is adjusted to an integer

number of sampling intervals. Command shaping has been applied to a wide range of flexible systems including disk drives, cranes, and large robot arms, such as the example by CAMotion (see VIDEO 777) as shown in Fig. 11.13. Note that this example contains a flexible drive belt, effectively a flexible joint, as well as flexible links that contribute to the compliance of the lowest mode that is quenched with an OAT filter.

Adaptive versions of command shaping have also been demonstrated. A version oriented toward repetitive motion applications is presented in [11.82].

Command Generation for Flexible Link Arms via Inverse Dynamics

In contrast to the scant system knowledge required for command shaping, the inverse dynamics of a flexible arm requires a great deal of knowledge about the system. The creation of an appropriate model was discussed above. An assumed modes model, for example, is well adapted to inverse dynamics if the rigid coordinates are not the joint angles, but the angles between lines connecting the joint axes (where it is assumed that joints are rotational). In this case, the desired end-of-arm motion can be expressed solely in terms of rigid variables, that is, the same variables q_d used in the flexible joint case, and the desired flexible variables are found from the second-order equations driven by the known rigid positions and velocities. The remaining difficulty is the unstable zero dynamics of the system.

For the purposes of introduction, only the linear situation will be treated here in the fashion of [11.83]. First, the rigid coordinates and their derivatives are found from the desired end-of-arm motion profile. The flexible equations are separated into causal stable zeros and anticausal unstable zeros, and the stable inverse is solved forward in time. Physically the motion response responds after the torque inputs. The computational input however is the response and the torque is calculated as an output, so no physical laws are violated in solving the anticausal portion beginning at the final time when flexible coordinates are specified to be zero and proceeding to the initial time and beyond. In fact, the exact solution extends from negative infinity (where the anticausal solution decays) to positive infinity (where the causal solution decays). For realistic dynamics, the necessary time for the input is only slightly more than the motion time for the end of the arm because the zeros are often quite far from the origin in both directions. If the end-of-arm motion begins at time zero, shortly before that, the joint torques begin to *pre-shape* the flexible links without moving the end of arm. Similarly, when the end of the arm reaches its final position, the joint torques must release the arm deflection in a manner that is not seen from the

Fig. 11.12 Block diagram representation of the command shaping algorithm

Fig. 11.13 A large flexible linking arm with command shaping

Fig. 11.14 Inverse dynamics driven motion of a single-link flexible arm

end of arm (or any other chosen output location). Figure 11.14 shows the example from Kwon [11.84] for a single-link arm and the VIDEO 778 shows the behavior improvement.

Since inversion of the flexible plant as described earlier containing nonminimum phase or *unstable* zeros can result in an anticausal input torque to achieve an arbitrary trajectory, it is appropriate to look for other trajectories with special characteristics that avoid these

problems. The location of zeros are dependent on where on the flexible link the trajectory is specified. *De Luca* et al. studied the one flexible link rotational arm and the migration of zeros as the point of interest is shifted from tip to joint. They utilize a point where zeros are nonexistent as the output point, a point that enables inversion to proceed without the causality problem [11.85–87]. When this point reaches the desired angle with zero deflection, the end point will also be at the desired angle. Joint velocity and deflection velocities must also be brought to zero resulting in a rest-to-rest motion completed in specified time and with no residual oscillations. The cited references show the equivalence of this development in the time or frequency domain for linear systems. For a two link arm (only the forearm is flexible), the nonlinear behavior demanded a time domain approach [11.86].

De Luca and *Di Giovanni* [11.85] address rest-to-rest motion of a single flexible link and carries through an example for a single flexible mode. The later reference [11.87] also provides experimental results for which a brief video (VIDEO 779) is available. The strength of this approach is its relative simplicity in achieving the desired final position described by a single polynomial. The degree of the single polynomial required to meet all the boundary conditions is $4n_c + 3$ where n_c is the number of flexible modes. One difficulty is the inability to efficiently constrain the peak torque required. Torque profiles developed in this simplest of strategies have high peaks but for most of the trajectory (at start and end) are relatively low. Hence the peak torque capabilities of the actuator may not be efficiently used. It is not necessary for a single polynomial to describe the entire trajectory, of course, but the complexity of developing the response without zeros becomes more challenging for piece wise polynomials, and arises from meeting all the boundary conditions on polynomial segments. The nonlinear case arising from a two link arm with the forearm flexible [11.86] provides further exploration of the inversion approach for flexible arms.

The model employed by *De Luca* varies slightly since deflection is measured from an axis passing through the dynamic center of mass of the flexible arm as shown in Fig. 11.15, not the tangent to the neutral axis of the beam at the rotary actuator. This modifies the boundary conditions on the shape equation and hence the mode shapes. For an introduction, a single flexible link is considered here. Variables are defined as follows:

- J_0, J_p : rotary inertia of the rotary actuator, tip payload, respectively
- m_p : mass of the tip payload

- $\theta, \theta_c, \theta_t$: angles through center of mass, tangent to actuated end, and through tip, respectively
- x : axis through the center of mass (COM)
- y : deflection perpendicular to x .

Consider the case with no damping on the modes. While modal damping is readily incorporated, its typically low values justify an abbreviated treatment here for the sake of space and simplicity. The output y specified is the sum of the angle (to the center of mass), the angular velocity, deflections and deflection rate, each times appropriate gains. These gains are found by specifying the transfer function from joint torque to y to be of maximum relative degree, i. e., it has no zeros. Equivalently, the successive derivatives of y do not explicitly involve the torque until the $(2n_c + 1)$ -th derivative. Note that these characteristics ascribed to differentially flat systems may yield a more complete understanding of this approach [11.88, 89],

$$\frac{y(s)}{\tau(s)} = \frac{K}{s^2 \prod_{i=1}^{n_c} (s^2 + \omega_i^2)},$$

$$K = \frac{1}{J} \prod_{i=1}^{n_c} \omega_i^2.$$

When transformed to the time domain, the resulting form of the torque based on derivatives of the desired output will be

$$\tau_d(t) = \frac{J}{\prod_{i=1}^{n_c} \omega_i^2} \left[y_d^{(2(n_c+1))}(t) + \sum_{i=0}^{2n_c-1} \alpha_i y_d^{(i+2)}(t) \right].$$

The α_i values are readily found from the convolution of the polynomial or expansion of the denominator of $y(s)/\tau(s)$. But what must be used for y_d ? With the given definition of y , the desired value of y_d for the rest-to-rest trajectory will be achieved by creating an interpolating trajectory with the desired initial and final values of y_d

Fig. 11.15 A definition of variables for the causal inversion of *De Luca*

and derivatives of y_d at the initial and final times that are zero. The number of derivatives to set equal to zero are at least $2n_e + 1$, but it may be preferred to set additional derivatives equal to zero to obtain a smoother torque at the ends of the trajectory. As explained in [11.85] this is a transformation of states that results also in the desired rest-to-rest behavior of the joint angle, the deflection and their derivatives. For more robustness, the feedforward command should be supplemented with feedback control, for example a simple PD or PID control of the joint angle to follow y_d .

Shown in Fig. 11.16 are the torque and resulting bending deflection for a 2.2 s move using this combination on a single link flexible arm [11.87].

To best comprehend these results, some details of the flexible arm in the experiment are needed. The desired trajectory was defined by a polynomial of degree 19. The arm length was 0.655 m, of sheet steel 2 mm thick and 51 mm wide, directly driven by a DC motor with inertia of $1.888 \times 10^{-3} \text{ kg m}^2$ and no tip mass. The resulting natural frequencies were 14.4, 13.2 and 69.3 Hz with damping ratios of 0.0001, 0.001, and 0.008, respectively. Frequency errors of the model were less than 1%. Friction compensation was applied based on static and viscous models of the friction under continuous rotation.

Feedback Control of Flexible Links

Flexibility in the links is in some cases controlled in the same way as concentrated flexibility in joints. Herein the focus is on approaches that apply specifically to link flexibility; consequently the use of Kalman filtering to estimate tip position and other broadly used techniques are not reexamined. A long history of research

on this topic exists. *Cannon and Schmitz* [11.90], *Truckenbrodt* [11.91], and others showed that these techniques work for flexible link arms and that the noncollocated nature of the system aggravates the sensitivity to modeling errors.

Strain measurements provide a valuable indication of the state of a flexible link, and strain rate, obtained from filtered differentiation of the typically noisy strain signal, was shown by *Hastings and Book* [11.92] to be an appropriate way of overcoming the limitations imposed by purely joint feedback control. *Yuan et al.* [11.93] produced an adaptive version of strain-rate feedback.

Strain measurements readily lend themselves to calculation of the modal amplitudes, and the number of appropriately placed strain gage measurements N can be equal to the number of mode amplitudes to be evaluated. In this case, no estimation algorithm is necessary, although filtering is usually needed. If the mode shape φ_i of a beam is known, strain is proportional to the second derivative of φ_i

$$\alpha_{ij} = \left. \frac{\partial^2 \varphi_i}{\partial x^2} \right|_{x_j} . \quad (11.85)$$

By inverting the coefficient matrix thus formed, it is simple to obtain the amplitude of N modes as

$$\begin{pmatrix} \delta_1 \\ \delta_2 \\ \vdots \\ \delta_N \end{pmatrix} = \begin{pmatrix} \alpha_{11} & \alpha_{12} & \dots & \alpha_{1N} \\ \alpha_{21} & \alpha_{22} & \dots & \alpha_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \alpha_{N1} & \alpha_{N2} & \dots & \alpha_{NN} \end{pmatrix}^{-1} \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_N \end{pmatrix} . \quad (11.86)$$

Fig. 11.16 (a) Applied torque for rest to rest motion with PD control. (b) Bending deformation at the tip

Additional attention is necessary if beam torsion is a significant part of the mode deflection, but the principle still applies. Active control of high-frequency modes may not be warranted, and feedback of the one or two lowest-frequency modes can be managed by classical or state-space design techniques to increase the damping of that mode.

The use of the measurement of the end-of-arm position has perpetual appeal and is very effective for rigid arms for the elimination of variability due to arm distortion and the change over time of arm calibration. Machine vision can eliminate uncertainty in the target position as well as the arm position. These approaches are plagued by the noncollocated and hence non-minimum-phase dynamics of link flexibility, however, and may require particular caution. Wang and Vidyasagar [11.94] proposed an alternative formulation of EOA measurements in the control formulation that he called the reflected tip position. For a rotating link of angle θ and length l , the deflected position is $l\theta + \delta$ while the reflected tip position $l\theta - \delta$ is minimum phase. This combination of joint and tip measure-

Fig. 11.17 Robotic arm large and flexible (RALF) used in EOA feedback experiments

ments produced the desired undeflected position but would not serve for EOA tracking control. Obergfell and Book [11.95] synthesized an output based on strain feedback combined with EOA position that allowed tracking control as well. They first produced a passive system with deflection feedback obtained from optical measurements of the link deflection, and then devised a traditional feedback control of the tip position measured by machine vision of the large two link arm shown in Fig. 11.17 for the experimental robot RALF (robot arm long and flexible). Figures 11.18 and 11.19 compare the path for a large square traced in a plane with only the deflection feedback and with both deflection and EOA position feedback.

Robust Estimation for Flexible Link Systems

The state feedback algorithms readily designed for linear flexible link systems are dependent on information about states that cannot be directly measured and are theoretically infinite in number. Truncation of the states to represent the most dominant low frequency modes is a ready solution to the second problem and state estimators or observers present a viable approach to the first problem. (Estimator and observer are commonly used interchangeably, but the term observer is more common will be used in this section.) For linear systems a Luenberger observer or the stochastically based Kalman filter are commonly used. Unfortunately, observers require an accurate system model or the estimates may be poor and the observer, a dynamic system

Fig. 11.18 Path followed without EOA position feedback. (Commanded trajectory is a square partially shown in light brown. Actual trajectory shown in dark brown)

of order as high as the order of the system itself, may even be unstable. Hence the robustness of the state observer is a critical subject for the control of flexible link systems. The quality of the control is ultimately the best measure of the quality of the estimator. Robust observer design has been the subject of considerable research and, in large part, mirrors the development of robust controllers. This is natural since an observer is a dynamic system which, like the plant itself, can be controlled to achieve a desired outcome. *Control effort* of the observer is utilized to drive convergence of the estimated outputs of the observer to the measured outputs of the real system. Hence research on estimators based on H-infinity, fuzzy logic, neural network, sliding mode, adaptive, and other design techniques abound. In this chapter, two types of observers will be discussed: sliding mode observers and multiple model observers.

For all observers the placement of sensors is crucial and for estimation of multiple modes it is desirable, although not theoretically essential, to use multiple sensors. Joint sensors (position and velocity) are typically available for general pose (joint) control, but for deflection sensing strain gages and accelerometers are currently most appropriate. The MEMS accelerometers now readily available and inexpensive will be the principle choice here. Strain gages are more fragile and generally provide more complex readings of the mode behavior. Accelerometers are complicated by the fact that acceleration is not dependent on just states z which include the mode amplitudes and their derivatives, but also on the input u creating the link motion. Acceleration measurement of a point p on the link is affected by both the states z and the input u as follows,

$$\ddot{x}_p = \left\{ -\beta(p)[\Phi][\omega^2] - \beta(p)[\Phi][\hat{C}] \right\} z + \left\{ \beta(p)[\Phi][\Phi]^T Q \right\} u,$$

where \ddot{x}_p is the acceleration in the direction perpendicular to the beam axis, Φ is the matrix of eigenvectors, z is the state vector, composed of joint motion as well as beam deflections, p is the location of the sensor along the beam axis, ω^2 is the diagonal matrix of natural frequencies squared, \hat{C} is the modal damping matrix, $\beta(p)$ expresses the sensor motion in terms of the modal states variables, and Q relates the input to the system states.

As Post [11.96] has explained, the ability of a given sensor to detect a mode depends on the amplitude of the mode at the sensor location. Overall the singular values of the observability grammian, also used for testing the system observability, is a reasonable but not perfect

Fig. 11.19 Path followed with EOA feedback from camera. (Commanded trajectory is a square partially shown in light brown. Actual trajectory shown in dark brown)

metric. A robust measurement requires the placement of sensors so as to avoid nodes (zero crossings) of the modes to be sensed even when parameters of the system change or are inaccurate. A single sensor (strain gage or accelerometer) is much more likely to have this problem than multiple sensors. The next sections depend on suitably placed sensors. For those modes not being controlled, one should minimize their influence by placing sensors near the node of those modes. This helps to avoid spillover of these modes that interferes with the system as approximated.

Parametric Errors in System Model

Parametric errors are inaccuracies in the parameters of a model with an accurate representation of the system structure. For flexible link systems this might arise from inaccurate payload mass, stiffness values, stiffness distribution, boundary conditions, etc., all of which lead to inaccurate mode shapes, natural frequencies and input coefficients. Errors are inevitable to some degree. As a consequence of parametric errors, one of the most powerful results of linear feedback control of estimated states, the separation principle which says the design of the observer does not change the eigenvalues of the controlled system and vice versa, is compromised. The rapid convergence of observer error to zero will in general not occur with parametric error. The net effect is a major blow to the effectiveness of the classical Luenberger observer. The Kalman filter, which optimizes observer gains under conditions of Gaussian process and measurement noise, is likewise

compromised. Without good state estimates the effectiveness of the powerful state feedback approaches are in jeopardy.

One currently popular tack to improve the robustness of observers is the sliding mode observer. There are several variations of this approach, and the technique by *Wallcot* and *Zak* [11.97, 98] was followed by *Post* [11.96] in exploring the consequences of parametric error. As typical, a sliding surface is defined which is intended to guide the estimate error to zero. The reaching phase moves from the initial error state to the sliding surface and when that surface is crossed the sign on the control changes. This rapid switching may be modified by establishing a *boundary layer* near the switching surface that substitutes a linear behavior.

In this section, we will use z as the state vector, \hat{z} as its estimate, L as the feedback of the observer, y as the measurement and K_s as the sliding mode gain. The *hat* on a variable will generally denote its estimate and an over dot its time derivative. The symbol Δ preceding a symbol indicates the variation of the true system parameter from its model. The linear plant model is thus

$$\dot{z} = Az + Bu; \quad y = Cz + Du.$$

The equation approaching the switching surface is

$$\dot{\hat{z}} = A\hat{z} + Bu + L(y - \hat{y}) + K_s \text{sgn}(y - \hat{y}).$$

When the boundary layer is included, the control is changed in a region near the switching surface where the design is essentially a conventional linear observer. For present purposes we will not employ a boundary layer but examine the pure sliding mode case, for which the error equation is

$$\dot{e} = A_0 e - K_s \text{sgn}(Ce) + \Delta Az + \Delta Bu,$$

which clearly has a steady state error solution that is not zero except in the case that $\Delta Az = -\Delta Bu$ which tends to occur when the overall system comes to rest. Thus the convergence of the sliding mode observer has similar issues found with the conventional linear observers. They can be stable but can converge to the wrong steady state value leading to error, particularly after the observer's state estimates should have converged to the slower changing system state. However, when the overall plant reaches steady state and $z = 0$, $u = 0$, the observer error will also converge to zero. In contrast, the usual intent is to design the observer to quickly converge to the true state estimate in order to appropriately control the plant.

Successful Estimation with Model Parameter Uncertainty

Models are seldom, if ever, exact in their representation of a physical system. In addition to error in parameter identification, parameters can change with time and operating conditions. For example, robots acquire and release payloads and move to different poses which may change parameters. As reported before, convergence of state observers is adversely affected by these changes which can lead to poor performance and even instability. In a recent work, *Post* [11.96] described a multiple model estimation scheme that successfully overcomes these limitations for a flexible link robot in both simulation and experiment. Other authors, e.g., *Chalhoub* and *Kfoury* [11.99] have used fuzzy logic techniques to address the needs for improving sliding mode observers.

Since the true state of the system is not known, the steady state estimation error cannot be calculated, but if it is known to exist, *Post* has shown it to be proportional to parameter error. Hence multiple models based on a different set of sensors can be used to establish which is most accurate. The difference in estimated states based on two sensor selections $\delta_z(t) = \hat{z}_{s_1} - \hat{z}_{s_2}$ is then a metric for choosing between alternative observers in an array of observers with different assumed parameters.

The observers themselves (conventional Luenberger observers or Kalman filters) have the form

$$\dot{\hat{z}}_{s_1}(t) = A\hat{z}_{s_1}(t) + Bu(t) + L_{s_1}[y_{s_1}(t) - \hat{y}_{s_1}(t)],$$

where \hat{z}_{s_1} is the estimate of the state vector z using the sensor array 1, A is the plant matrix, B is the input matrix, L_{s_1} is the gain matrix to be designed, y_{s_1} is the sensor measurement of sensor array 1, and \hat{y}_{s_1} estimate of sensor measurement of sensor array 1, and similarly for sensor s_2 . The difference between states and their estimates converges rapidly (relative to the states themselves) to steady state and hence $\hat{z}_{s_1} - \hat{z}_{s_2}$ converges to zero and hence

$$\begin{aligned} \delta_z(t) = & \chi_1[\Delta Az(t) + \Delta Bu] \\ & + \chi_2[\Delta C_{s_1}z(t) + \Delta D_{s_1}u(t)] \\ & + \chi_3[\Delta C_{s_2}z(t) + \Delta D_{s_2}u(t)] \end{aligned}$$

is found to be the *steady state* slowly changing (relative to the observer dynamics) difference in the two observers based on sensors s_1 and s_2 . Here, the χ_i are constant matrices based on the model parameters and not the true values of the system. Δ indicates the deviation of the true matrices from the model's matrices following that symbol. Note that subscripts s_1 and s_2 indicate different sensors involved in the measurement

and feed through matrices C and D , respectively. Also note that this equation is somewhat complicated by the feedthrough matrices occurring due to the use of accelerometers to sense the motion.

Incorporating the specific representation of a linear flexible manipulator, the equations are

$$\dot{z} = \begin{pmatrix} 0_{(n \times n)} & I_{(n \times n)} \\ -\omega_{(n \times n)}^2 & -\hat{C}_{(n \times n)} \end{pmatrix} z + \begin{pmatrix} 0_{(n \times m)} \\ \hat{Q}_{(n \times m)} \end{pmatrix} u,$$

where \hat{C} denotes modal damping and \hat{Q} denotes the modal forcing coefficient. The sensor's output is

$$y_{Si} = \left\{ -[1, \psi_1(p_{si}), \dots, \psi_n(p_{si})] \Phi_{(n \times n)} \omega_{(n \times n)}^2 \right. \\ \left. - [1, \psi_1(p_{si}), \dots, \psi_n(p_{si})] \Phi_{(n \times n)} \hat{C}_{(n \times n)} \right\} z \\ + [1, \psi_1(p_{si}), \dots, \psi_n(p_{si})] \Phi_{(n \times n)} \hat{Q}_{(n \times n)} u.$$

Let $\beta_{Si} = [1, \psi_1(p_{si}), \dots, \psi_n(p_{si})]$ and one can attribute to the sub-matrices the parametric change matrices

$$(\Delta A z(t) + \Delta B u) = \\ \begin{pmatrix} 0_{(n \times n)} \\ I_{(n \times n)} \end{pmatrix} \left[(-\Delta \omega^2 - \Delta \hat{C}) z(t) + \Delta \hat{Q} u(t) \right], \\ (\Delta C_{Si} z(t) + \Delta D_{Si} u) = \\ \beta_{Si} \Phi \left[(-\Delta \omega^2 - \Delta \hat{C}) z(t) + \Delta \hat{Q} u(t) \right], \\ \delta_z(t) = \left[\chi_1 \begin{pmatrix} 0_{(n \times n)} \\ I_{(n \times n)} \end{pmatrix} + \chi_2 \beta_{s1} \Phi + \chi_3 \beta_{s2} \Phi \right] \\ \times \left[(-\Delta \omega^2 - \Delta \hat{C}) z(t) + \Delta \hat{Q} u \right],$$

which will be coalesced to give

$$\delta_z(t) = \Lambda_{(2n \times n)} \gamma(t),$$

where it can be seen that Λ consists of known model parameters and γ is an unknown metric of parameter errors that can't be solved from this equation. However, using the pseudo inverse we can produce a least squares metric $\gamma_m(t)$ which evaluates the relative accuracy of two observers based on different models

$$(\Lambda^T \Lambda)^{-1} \Lambda^T \delta_z^*(t) = \gamma_m(t).$$

The smaller the norm of $\gamma_m(t)$, the more accurate the observer based on a given model is expected to be.

While various methods of using $\gamma_m(t)$ can be contrived, *Post* [11.96] utilized a switching approach he referred to as the multiple model switching adaptive estimator (MMSAE), visualized in Fig. 11.20. The weighting value w_i is based on $\gamma_{mi}(t)$ for the observer

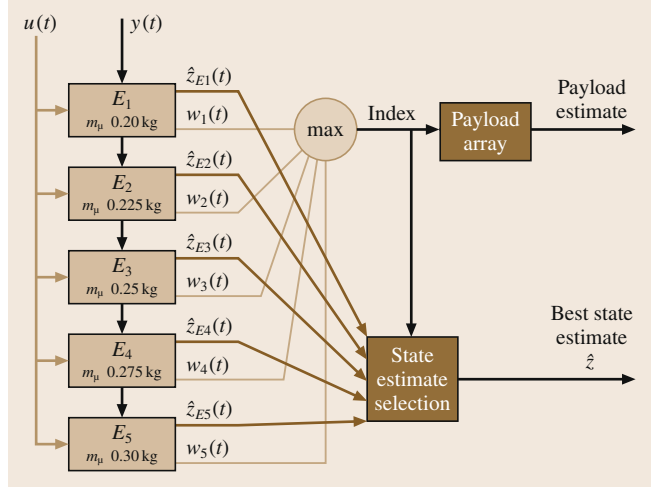

Fig. 11.20 Flow chart for the multiple model switching adaptive estimator (MMSAE)

based on a given model, then the estimate \hat{z}_i from that observer was used. Figure 11.21 shows schematically the flow inside the estimator blocks E_1 through E_5 . The parameter varied in Post's experiments was arm payload. Multiple parameters could be varied but would lead to a higher dimensional formulation and poten-

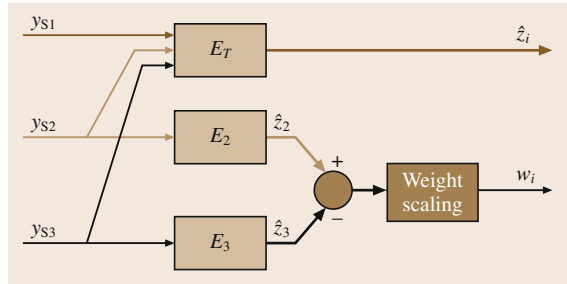

Fig. 11.21 Estimation module with weight scaling

Fig. 11.22 Gantry robot used in MMSAE experiments (after *Post* [11.96])

tially many estimators numbering $N_T = N_1 N_2 \cdots N_p$ for the variation of p parameters, each with N_i values represented.

Post [11.96] conducted experiments with a linear model of the gantry robot as illustrated in Fig. 11.22 and schematically modeled in Fig. 11.23, with the parameters given in Table 11.1 and sensor placements at 0.015, 0.25, and 0.42 m from the actuated end of the beam. He compared:

- Conventional PID (VIDEO 780).
- Fixed gain linear-quadratic regulator (LQR) plus Luenberger state space designs (VIDEO 781).
- MMSAE design observers and LQR controls. Five potential payloads were chosen with spacing in even increments between 0.2 and 0.3 kg, i.e., an end-point mass between 0.35 and 0.55.

The penalty matrices were kept the same for the LQR controls but the resulting gains changed based on the model employed by the MMSAE selection. While various measures of performance could be demonstrated involving somewhat arbitrary selection of con-

troller types, controller gains and metrics, the following characteristics are considered most critical:

- Stability with various payloads.
- Cycle completion time, with requirements for settling of vibration amplitude at prescribed stops.
- Variation of cycle times with changing payloads.

Since reasonable work cycles often pick up and drop off payloads, the test included these operations. Cycle times are graphed in Fig. 11.24. The light bars show the cycle times for the complete cycle with segments of the task carrying the payload and others with the gripper empty. The dark bars show operation with no payload carried and only the gripper mass present for the entire cycle. In addition to the pair of bars labeled PID and MMSAE (with obvious meanings) are pairs labeled SS 0.25 through SS 0.40. These latter labels refer to the *designed-for* tip mass (payload plus gripper). The most obvious message from this figure is that the state space control is a vast improvement over PID, reducing cycle time by about 90%. What is not obvious from this figure is that some means of gain change is needed to accommodate the payload variations. With a designed-for tip mass of 0.45 kg and above, the operation without payload was unstable. This is still below the actual tip mass of 0.5 kg. Hence MMSAE was essential for a successful completion of the task with these design criteria (i.e., LQR penalty matrices and resulting gains). The exact tip mass does not need to be known, only the range of masses. The near identical cycle times with and without the additional payload seen on the chart for MMSAE is also a practical advantage.

11.2.4 Further Reading

The topic of flexible link robot control is widely covered with papers on modeling and control. The reader wishing to probe further may want to begin with a paper giving some perspective on the nature of the problem. This was the goal of Book in [11.100]. Progress to date in this field from the theoretical perspective is signifi-

Table 11.1 Parameters of the gantry robot model

Parameter	Value	Unit
Payload (m_t)	0.281	kg
Cart mass (m_c)	10	kg
Arm length (L)	0.42	m
Elastic modulus (E)	7×10^{-10}	N/m
Density (ρ)	2700	kg/m ³
Area moment (I)	1.0114×10^{-10}	m ⁴
Belt stiffness (K_b)	2.1814×10^5	N/m
Cart damper (C_d)	100	N s/m
Structural damping coefficient (γ)	0.0005	N s/m

cant and has been collected by *Canudas de Witt* et al. in [11.101]; this reference includes a wide range of research approaches, but the examples of the practical application of this theory are more limited. The German Aerospace Center has produced lightweight space arms [11.102] and deployed them in space. The startup CAMotion, Inc. [11.103] has produced large lightweight industrial robots using the command-shaping approach to improve cycle time. High-speed arms such as the FlexPicker [11.104] achieve a light weight and avoid flexibility because of their parallel structure, but suffer the usual disadvantages of parallel actuation: restricted workspace considering the space occupied by the robot structure.

Trautt and *Bayo*'s early exploration of non-minimum-phase inverses is described in [11.105]. This is a particularly interesting variation of the work by

Kwon [11.83, 84] in that it uses the frequency domain and deals with nonzero initial conditions. The concept of using two time scales, a fast time scale for the flexible dynamics and a slow time scale for the rigid dynamics, can be found in *Siciliano* and *Book* [11.106]. The singular perturbation approach was used earlier by *Spong* for elastic joint arms. *Ghorbel* and *Spong* also consider flexible links and contact with a rigid environment in [11.107]. Achieving robustness is a problem, particularly with end-point sensors. Sliding mode control [11.108] and passivity-based control [11.109] address this problem in effective but widely varying ways. While these seem to be the more promising methods of control, one will find many more approaches to this challenging control problem. H_∞ , adaptive, fuzzy, and other controllers have all been applied with varying degrees of success.

12. Robotic Systems Architectures and Programming

David Kortenkamp, Reid Simmons, Davide Brugali

Robot software systems tend to be complex. This complexity is due, in large part, to the need to control diverse sensors and actuators in real time, in the face of significant uncertainty and noise. Robot systems must work to achieve tasks while monitoring for, and reacting to, unexpected situations. Doing all this concurrently and asynchronously adds immensely to system complexity.

The use of a well-conceived architecture, together with programming tools that support the architecture, can often help to manage that complexity. Currently, there is no single architecture that is best for all applications – different architectures have different advantages and disadvantages. It is important to understand those strengths and weaknesses when choosing an architectural approach for a given application.

This chapter presents various approaches to architecting robotic systems. It starts by defining terms and setting the context, including a recounting of the historical developments in the area of robot architectures. The chapter then discusses in more depth the major types of architectural components in use today – behavioral control (Chap. 13), executives, and task planners (Chap. 14) – along with commonly used techniques for interconnecting connecting those components. Throughout, emphasis will be placed on programming tools and environments that support these architectures. A case study is then presented, followed by a brief discussion of further reading.

12.1 Overview

The term *robot architecture* is often used to refer to two related, but distinct, concepts. Architectural *struc-*

ture refers to how a system is divided into subsystems and how those subsystems interact. The structure of

a robot system is often represented informally using traditional *boxes and arrows* diagrams or more formally using techniques such as unified modeling language (UML) [12.1]. In contrast, architectural *style* refers to the computational concepts that underlie a given system. For instance, one robot system might use a publish–subscribe message passing style of communication, while another may use a more synchronous client–server approach.

All robotic systems use some architectural structure and style. However, in many existing robot systems it is difficult to pin down precisely the architecture being used. In fact, a single robot system will often use several styles together. In part, this is because the system implementation may not have clean subsystem boundaries, blurring the architectural structure. Similarly, the architecture and the domain-specific implementation are often intimately tied together, blurring the architectural style(s).

This is unfortunate, as a well-conceived, clean architecture can have significant advantages in the specification, execution, and validation of robot systems. In general, robot architectures facilitate development by providing beneficial constraints on the design and implementation of robotic systems, without being overly restrictive. For instance, separating behaviors into modular units helps to increase understandability and reusability, and can facilitate unit testing and validation.

12.1.1 Special Needs of Robot Architectures

In some sense, one may consider robot architectures as software engineering. However, robot architectures are distinguished from other software architectures because of the special needs of robot systems. The most important of these, from the architectural perspective, are that robot systems need to interact asynchronously, in real time, with an uncertain, often dynamic, environment. In addition, many robot systems need to respond at varying temporal scopes – from millisecond feedback control to minutes, or hours, for complex tasks.

To handle these requirements, many robot architectures include capabilities for acting in real time, controlling actuators and sensors, supporting concurrency, detecting and reacting to exceptional situations, dealing with uncertainty, and integrating high-level (symbolic) planning with low-level (numerical) control.

While the same capability can often be implemented using different architectural styles, there may be advantages of using one particular style over another. As an example, consider how a robot system’s style

of communications can impact on its reliability. Many robot systems are designed as asynchronous processes that communicate using message passing. One popular communication style is *client–server*, in which a message request from the client is paired with a response from the server. An alternate communication paradigm is *publish–subscribe*, in which messages are broadcast asynchronously and all modules that have previously indicated an interest in such messages receive a copy. With client–server-style message passing, modules typically send a request and then block, waiting for the response. If the response never comes (e.g., the server module crashes) then deadlock can occur. Even if the module does not block, the control flow still typically expects a response, which may lead to unexpected results if the response never arrives or if a response to some other request happens to arrive first. In contrast, systems that use publish–subscribe tend to be more reliable: because messages are assumed to arrive asynchronously, the control flow typically does not assume any particular order in which messages are processed, and so missing or out-of-order messages tend to have less impact.

12.1.2 Modularity and Hierarchy

One common feature of robot architectures is modular decomposition of systems into simpler, largely independent pieces. As mentioned above, robot systems are often designed as communicating processes, where the communications interface is typically small and relatively low bandwidth. This design enables the processes/modules to handle interactions with the environment asynchronously, while minimizing interactions with one another. Typically, this decreases overall system complexity and increases overall reliability.

Often, system decomposition is hierarchical – modular components are themselves built on top of other modular components. Architectures that explicitly support this type of layered decomposition reduce system complexity through abstraction. However, while hierarchical decomposition of robotic systems is generally regarded as a *desirable quality*, debate continues over the dimensions along which to decompose. Some architectures [12.2] decompose along a temporal dimension – each layer in the hierarchy operates at a characteristic frequency an order of magnitude slower than the layer below. In other architectures [12.3–6], the hierarchy is based on task abstraction – tasks at one layer are achieved by invoking a set of tasks at lower levels. In some situations, decomposition based on spatial abstraction may be more useful, such as when dealing with both local and global navigation [12.7]. The main point is that different applications need to decompose

problems in different ways, and architectural styles can often be found to accommodate those different needs.

12.1.3 Software Development Tools

While significant benefit accrues from *designing* systems using well-defined architectural styles, many architectural styles also have associated software tools that facilitate adhering to that style during *implementation*. These tools can take the form of libraries of functions calls, specialized programming languages, or graphical editors. The tools make the constraints of the architectural style explicit, while hiding the complexity of the underlying concepts.

For instance, inter-process communication libraries, such as common object request broker architecture (CORBA) [12.8] and inter-process communication (IPC) package [12.9], make it easy to implement message passing styles, such as client–server and publish–subscribe, respectively. Languages, such as Subsumption [12.10] and Skills [12.11] facilitate the

development of data-driven, real-time behaviors, while languages such as the execution support language (ESL) [12.12] and the plan execution interchange language (PLEXIL) [12.13] provide support for reliably achieving higher-level tasks. Graphical editors, such as found in ControlShell [12.14], Labview [12.15] and open robot controller computer aided design (ORCCAD) [12.6], provide constrained ways to assemble systems, and then automatically generate code that adheres to the architectural style.

In each case, the tools facilitate the development of software in the given style and, more importantly, make it impossible (or, at least, very difficult) to violate the constraints of that architectural style. The result is that systems implemented using such tools are typically easier to implement, understand, debug, verify, and maintain. They also tend to be more reliable, since the tools provide well-engineered capabilities for commonly needed control constructs, such as message passing, interfacing with actuators and sensors, and handling concurrent tasks.

12.2 History

Robot architectures and programming began in the late 1960s with the Shakey robot at Stanford University [12.16] (Fig. 12.1). Shakey had a camera, a range finder, and bump sensors, and was connected to DEC PDP-10 and PDP-15 computers via radio and video links. Shakey’s architecture was decomposed into three functional elements: sensing, planning, and executing [12.17]. The sensing system translated the camera image into an internal world model. The planner took the internal world model and a goal and generated a plan (i.e., a series of actions) that would achieve the goal. The executor took the plan and sent the actions to the robot. This approach has been called the *sense–plan–act* (SPA) paradigm (Fig. 12.2). Its main architectural features are that sensing flowed into a world model, which was then used by the planner, and that plan was executed without directly using the sensors that created the model. For many years, robotic control architectures and programming focused almost exclusively on the SPA paradigm.

12.2.1 Subsumption

In the early 1980s, it became apparent that the SPA paradigm had problems. First, planning in any real-world domain took a long time, and the robot would be blocked, waiting for planning to complete. Second, and more importantly, execution of a plan without in-

volving sensing was dangerous in a dynamic world. Several new robot control architecture paradigms be-

Fig. 12.1 Shakey (after [12.18])

Fig. 12.2 The sense–plan–act (SPA) paradigm (after [12.3], with permission)

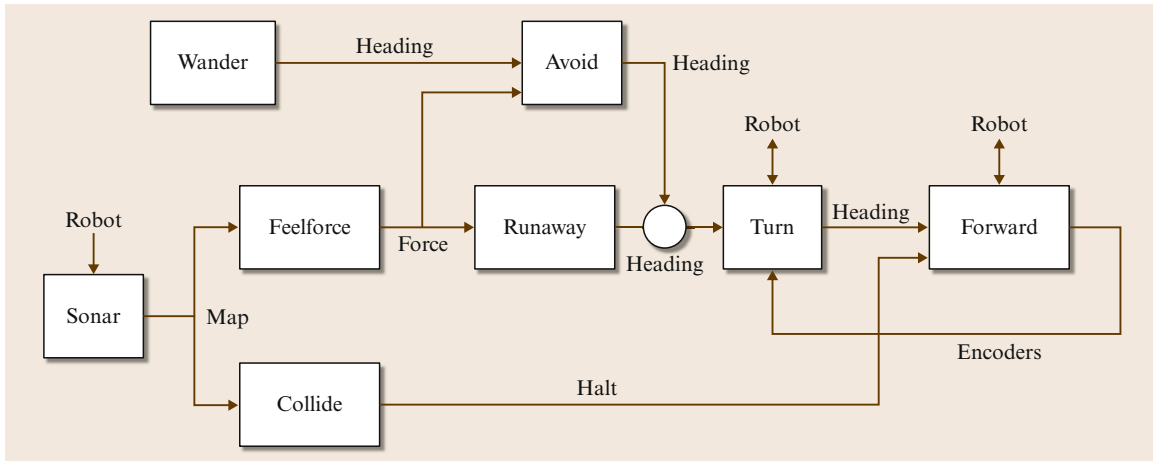

Fig. 12.3 Example of the Subsumption architecture (after [12.3])

gan to emerge, including reactive planning, in which plans were generated quickly and relied more directly on sensed information instead of internal models [12.4, 19]. The most influential work, however, was the subsumption architecture of Brooks [12.3]. A subsumption architecture is built from layers of interacting finite-state machines – each connecting sensors to actuators directly (Fig. 12.3). These finite-state machines were called *behaviors* (leading some to call Subsumption *behavior-based* or *behavioral* robotics [12.20]; see also Chap. 38). Since multiple behaviors could be active at any one time, Subsumption had an *arbitration* mechanism that enabled higher-level behaviors to override signals from lower-level behaviors. For example, the robot might have a behavior that simply drives the robot in random directions. This behavior is always active and the robot is always driving somewhere. A second, higher-level behavior could take sensor input, detect obstacles, and steer the robot away from them. It is also always active. In an environment with no obstacles, the higher-level behavior never generates a signal. However, if it detects an obstacle it overrides the lower-level behavior and steers the robot away. As soon as the obstacle is gone (and the higher-level behavior stops sending signals), the lower-level behavior gets control again. Multiple, interacting layers of behaviors could be built to produce more and more complex robots.

Many robots were built using the subsumption approach – most at MIT [12.21–23]. They were quite successful. Whereas SPA robots were slow and ponderous, Subsumption robots were fast and reactive. A dynamic world did not bother them because they constantly sensed the world and reacted to it. These robots scampered around like insects or small rodents. Several behavioral architectures arose in addition to

Subsumption, often with different arbitration schemes for combining the outputs of behaviors [12.24, 25].

A popular example of behavior-based architectures is Arkin's motor-control schemas [12.26]. In this biologically inspired approach, motor and perceptual schemas [12.27] are dynamically connected to one another. The motor schemas generate response vectors based on the outputs of the perceptual schemas, which are then combined in a manner similar to potential fields [12.28]. To achieve more complex tasks, the autonomous robot architecture (AuRA) architecture [12.29, 30] added a navigation planner and a plan sequencer, based on finite-state acceptors (FSAs), to the reactive schemas.

However, behavior-based robots soon reached limits in their capabilities. It proved very difficult to compose behaviors to achieve long-range goals and it proved almost impossible to optimize robot behavior. For example, a behavior-based robot that delivered mail in an office building could easily be built by simply wandering around the office building and having behaviors looking for rooms and then overriding the wandering and entering the office. It was much more difficult to use the behavioral style of architecture to design a system that reasoned about the day's mail to visit the offices in an optimal order to minimize delivery time. In essence, robots needed the planning capabilities of the early architectures wedded to the reactivity of the behavior-based architectures. This realization led to the development of layered, or tiered, robot control architectures.

12.2.2 Layered Robot Control Architectures

One of the first steps towards the integration of reactivity and deliberation was the reactive action packages

(RAPs) system created by *Firby*. In his thesis [12.31], we see the first outline of an integrated, three-layer architecture. The middle layer of that architecture, and the subject of the thesis, was the RAPs system. *Firby* also speculated on the form and function of the other two tiers, specifically with the idea of integrating classic deliberative methods with the ideas of the emerging situated reasoning community, but those layers were never implemented. Later, *Firby* would integrate RAPs with a continuous low-level control layer [12.32].

Independently and concurrently, *Bonasso* at MITRE [12.33] devised an architecture that began at the bottom layer with robot behaviors programmed in the Rex language as synchronous circuits [12.34]. These Rex machines guaranteed consistent semantics between the agent's internal states and those of the world. The middle layer was a conditional sequencer implemented in the goal as parallel programs (GAPPs) language [12.35], which would continuously activate and deactivate the Rex skills until the robot's task was complete. This sequencer based on GAPPs was appealing because it could be synthesized through more traditional planning techniques [12.36]. This work culminated in the three tiers (3T) architecture (named after its three tiers of interacting control processes – planning, sequencing, and real-time control), which has been used on many generations of robots [12.37].

Architectures similar to 3T (Fig. 12.4) have been developed subsequently. One example is a three layer architecture for navigating through intricate situations (ATLANTIS) [12.38], which leaves much more control at the sequencing tier. In ATLANTIS, the deliberative tier must be specifically called by the sequencing tier. A third example is *Saridis*' intelligent control architecture [12.39]. The architecture begins with the servo systems available on a given robot and augments them to integrate the execution algorithms of the next level, using VxWorks and the VME (Versa Module Europa) bus. The next level consists of a set of coordinating routines for each lower subsystem, e.g., vision, arm motion, and navigation. These are implemented in Petri net transducers (PNTs), a type of scheduling mechanism, and activated by a dispatcher connected to the organizational level. The organizational level is a planner implemented as a Boltzmann neural network. Essentially the neural network finds a sequence of actions that will match the required command received as text input, and then the dispatcher executes each of these steps via the network of PNT coordinators.

The LAAS architecture for autonomous systems (LAAS) is a three-layered architecture that includes software tools to support development/programming at each layer [12.40]. The lowest layer (functional) con-

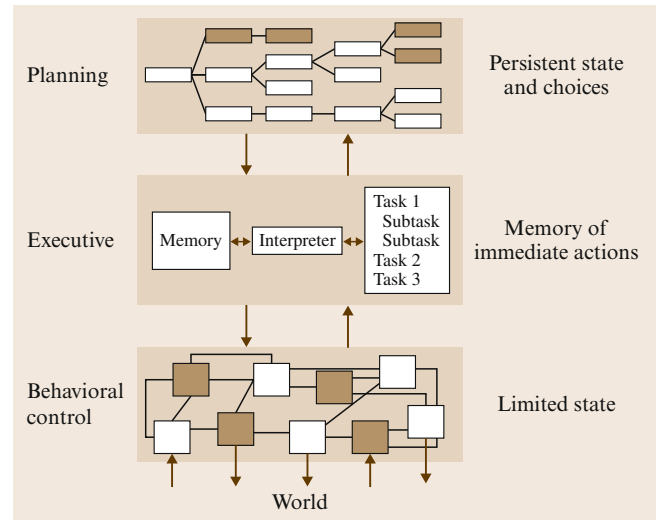

Fig. 12.4 Prototype three-tiered architecture

sists of a network of *modules*, which are dynamically parameterized control and perceptual algorithms. Modules are written in the generator of modules (GenoM) language, which produces standardized templates that facilitate the integration of modules with one another. Unlike most other three-layered architectures, the executive layer is fairly simple – it is purely reactive and does no task decomposition. It serves mainly as a bridge – receiving task sequences from the highest layer and selecting and parameterizing tasks to send to the functional layer. The executive is written in the Kheops language, which automatically generates decision networks that can be formally verified. At the top, the decision layer consists of a planner, implemented using the indexed time table (IxTeT) temporal planner [12.41, 42], and a supervisor, implemented using procedural reasoning system (PRS) [12.43, 44]. The supervisor is similar to the executive layer of other three-layered architectures – it decomposes tasks, chooses alternative methods for achieving tasks, and monitors execution. By combining the planner and supervisor in one layer, LAAS achieves a tighter connection between the two, enabling more flexibility in when, and how, replanning occurs. The LAAS architecture actually allows for multiple decisional layers at increasingly higher levels of abstraction, such as a high-level *mission* layer and a lower-level *task* layer.

Remote agent is an architecture for the autonomous control of spacecraft [12.45]. It actually consists of four layers – a control (behavioral) layer, an executive, a planner/scheduler, and mode identification and recovery (MIR) that combines fault detection and recovery. The control layer is the traditional spacecraft real-time control system. The executive is the core of

the architecture – it decomposes, selects, and monitors task execution, performs fault recovery, and does resource management, turning devices on and off at appropriate times to conserve limited spacecraft power. The planner/scheduler is a batch process that takes goals, an initial (projected) state, and currently scheduled activities, and produces plans that include flexible ranges on start and end times of tasks. The plan also includes a task to reinvoke the planner to produce the next plan segment. An important part of the remote agent is configuration management – configuring hardware to support tasks and monitoring that the hardware remains in known, stable states. The role of configuration management is split between the executive, which uses reactive procedures, and **MIR**, which uses declarative models of the spacecraft and deliberative algorithms to determine how to reconfigure the hardware in response to detected faults [12.46].

The Syndicate architecture [12.47] extends the 3T model to multirobot coordination (Chap. 51). In this architecture, each layer interfaces not only with the layers above and below, as usual, but also with the layers of the other robots at the same level (Fig. 12.5). In this way, distributed control loops can be designed at multiple levels of abstraction. The version of Syndicate in [12.48] used a distributed market-based approach for task allocation at the planning layer.

Other noteworthy multitiered architectures have appeared in the literature. The National Bureau of Standards (NBS) developed for the Aeronautics and Space Agency (NASA) the **NASA/NBS** standard reference model (**NASREM**) [12.2, 49], later named real-time control system (**RCS**), was an early reference model for telerobotic control (Fig. 12.6). It is a many-tiered model in which each layer has the same general structure, but operates at increasingly lower frequency as it moves from the servo level to the reasoning levels. With the exception of maintaining a global world

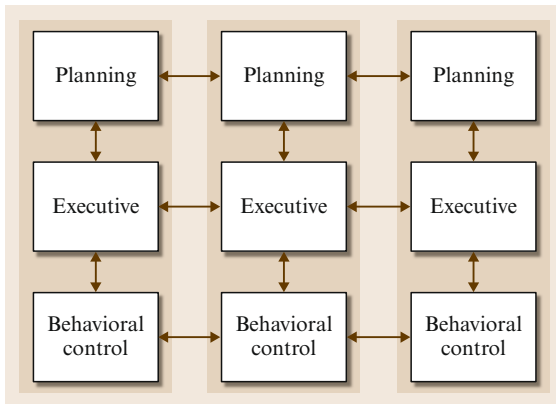

Fig. 12.5 The Syndicate multirobot architecture

model, **NASREM**, in its original inception, provided for all the data and control paths that are present in architectures such as 3T, but **NASREM** was a reference model, not an implementation. The subsequent implementations of **NASREM** followed primarily the traditional sense–plan–act approach and were mainly applied to telerobotic applications, as opposed to autonomous robots. A notable exception was the early work of *Blidberg/Chappell* [12.50].

While three-layered robot architectures are very popular, various two-layered architectures have been investigated by researchers. The coupled layered architecture for robot autonomy (**CLARAty**) was designed to provide reusable software for NASA's space robots, especially planetary rovers [12.52, 53]. **CLARAty** consists of a functional and a decision layer. The functional layer is a hierarchy of object-oriented algorithms that provide more and more abstract interfaces to the robot, such as motor control, vehicle control, sensor-based navigation, and mobile manipulation. Each object provides a generic interface that is hardware independent, so that the same algorithms can run on different hardware. The decision layer combines planning and executive capabilities. Similar to the LAAS architecture,

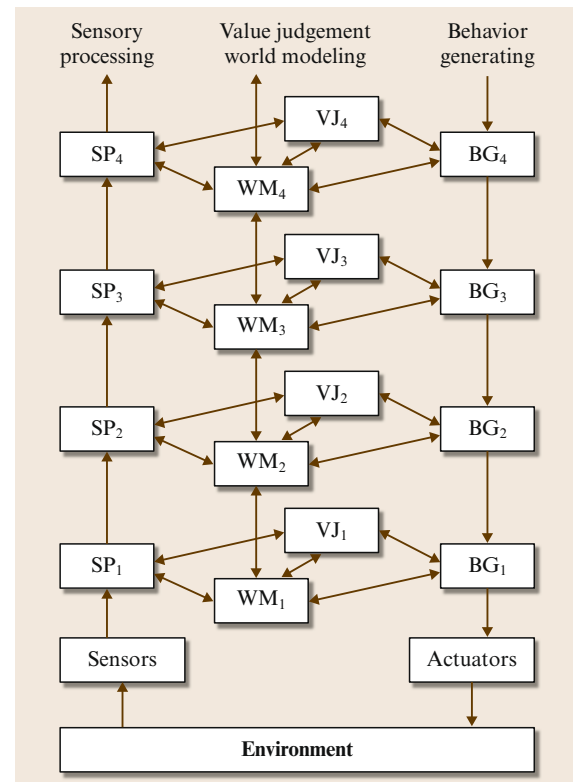

Fig. 12.6 The real-time control system (**RCS**) reference architecture (after [12.51])

this is done to provide for tighter coordination between planning and execution, enabling continual replanning in response to dynamic contingencies.

Closed-loop execution and recovery (CLEaR) [12.54] is one instantiation of the CLARAty decision layer. CLEaR combines the continuous activity scheduling, planning, execution and replanning (CASPER) repair-based planner [12.55] and the task description language (TDL) executive language [12.56]. CLEaR provides a tightly coupled approach to goal- and event-driven behavior. At its heart is the capability to do fast, continuous replanning, based on frequent state and resource updates from execution monitoring. This enables the planner to react to many exceptional situations, which can be important in cases where there are many tasks, few resources, and significant uncertainty. In CLEaR, both the planning and executive components are able to handle resource conflicts and exceptional situations – heuristics are used to decide which component should be involved in a given situation. The onboard autonomous science investigation system (OASIS) system [12.57] extends CLEaR to include science data analysis so that the architecture can be driven by opportunistic science-related goals (such as finding unusual rocks or formations). OASIS is planner-centric, releasing tasks to the executive component just a few seconds before their scheduled start times.

The cooperative intelligent real-time control architecture (CIRCA) is a two-layered architecture concerned with guaranteeing reliable behavior [12.58, 59]. It embodies the notion of *bounded reactivity* – an acknowledgement that the resources of the robot are not

always sufficient to guarantee that all tasks can be achieved. CIRCA consists of a real-time system (RTS) and an artificial intelligence (AI) system (AIS) that are largely independent. The RTS executes a cyclic schedule of test action pairs (TAPs) that have guaranteed worst-case behavior in terms of sensing the environment and conditionally acting in response. It is the responsibility of the AIS to create a schedule that is guaranteed to prevent catastrophic failures from occurring, while running in hard real time. The AIS does this by planning over a state-transition graph that includes transitions for actions, exogenous events, and the passage of time (e.g., if the robot waits too long, bad things can happen). The AIS tests each plan (set of TAPs) to see if it can actually be scheduled. If not, it alters the planning model, either by eliminating tasks (based on goal prioritization) or by changing parameters of behaviors (e.g., reducing the robot's velocity). The AIS continues this until it finds a plan that can be successfully scheduled, in which case it downloads the new plan to the RTS in an atomic operation.

Like CIRCA, ORCCAD is a two-layered architecture that is concerned with guaranteed reliability [12.6, 60]. In the case of ORCCAD, this guarantee is achieved through formal verification techniques. Robot tasks (lower-level behaviors) and robot procedures (higher-level actions) are defined in higher-level languages that are then translated into the Esterel programming language [12.61], for logical verification, or the Timed-Argus language [12.62], for temporal verification. The verification is geared toward liveness and safety properties, as well as verifying lack of contention for resources.

12.3 Architectural Components

We will take the three-tiered architecture as the prototype for the components discussed in this chapter. Figure 12.4 shows a typical three-tiered architecture. The lowest tier (or layer) is behavioral control and is the layer tied most closely to sensors and actuators. The second tier is the executive layer and is responsible for choosing the current behaviors of the robot to achieve a task. The highest tier is the task-planning layer and it is responsible for achieving long-term goals of the robot within resource constraints. Using the example of an office delivery robot, the behavioral layer is responsible for moving the robot around rooms and hallways, for avoiding obstacles, for opening doors, etc. The executive layer coordinates the behavioral layer to achieve tasks such as leaving a room, going to an office, etc. The task-planning layer is responsible for decid-

ing the order of deliveries to minimize time, taking into account delivery priorities, scheduling, recharging, etc. The task-planning layer sends tasks (e.g., exit the room, go to office 110) to the executive. All these tiers need to work together and exchange information. The next section deals with the problem of connecting components to each other. We then discuss each component of the three-tiered prototype architecture in detail.

12.3.1 Connecting Components

All of the architecture components that have been discussed in this chapter need to communicate with each other. They need to both exchange data and send commands. The choice of how components communicate (often called the *middleware*) is one of the most im-

portant and most constraining of the many decisions a robot architecture designer will make. From previous experience, a great deal of the problems and a majority of the debugging time in developing robot architectures have to do with communication between components. In addition, once a communication mechanism is chosen it becomes extremely difficult to change, so early decisions persist for many years. Many developers *roll their own* communication protocols, usually built on top of Unix sockets. While this allows for customization of messages, it fails to take advantage of the reliability, efficiency, and ease of use that externally available communication packages provide. There are two basic approaches to communication: client–server and publish–subscribe.

Client–Server

In a client–server (also called a point-to-point) communication protocol, components talk directly with other components. A good example of this is remote procedure call (RPC) protocols in which one component (the client) can call functions and procedures of another component (the server). A modern, and popular, variation on this is the common object request broker architecture (CORBA). CORBA allows for one component to call object methods that are implemented by another component. All method calls are defined in an interface definition language (IDL) file that is language independent. Every component uses the same IDL to generate code that compiles with component to handle communication. The advantage of this is that, when an IDL file is changed, all components that use that IDL can be recompiled automatically (by using *make* or similar code configuration tools). CORBA object request brokers (ORBs) are available for most major object-oriented languages. Although free ORBs are available, many commercial ORBs offer additional features and support. One disadvantage of CORBA is that it introduces quite a bit of additional code into applications. Some competitors have tried to address this issue, such as the internet communications engine (ICE), which has its own version of an IDL file called the specification language for ICE (SLICE). The biggest advantage of a client–server protocol is that the interfaces are very clearly defined in advance and everyone knows when the interface has changed. Another advantage is that it allows for a distributed approach to communication with no central module that must distribute data. A disadvantage of client–server protocols is that they introduce significant overhead, especially if many components need the same information. It should be noted that CORBA and ICE also have a broadcast mechanism (called an event channel, or the notification service, in CORBA).

Publish–Subscribe

In a publish–subscribe (also called a broadcast) protocol, a component publishes data and any other component can subscribe to that data. Typically, a centralized process routes data between publishers and subscribers. In a typical architecture, most components both publish information and subscribe to information published by other components. There are several existing publish–subscribe middleware solutions. A popular one for robotics is the real-time innovations’ (RTI) data distribution service (DDS), formerly the network data distribution service (NDDS) [12.63]. Another popular publish–subscribe paradigm is IPC developed at Carnegie Mellon University [12.9]. Many publish–subscribe protocols are converging on using extensible markup language (XML) descriptions to define the data being published, with the added convenience of transmitting XML over HTTP, which allows for significant interoperability with Web-based applications. Publish–subscribe protocols have a large advantage in being simple to use and having low overhead. They are especially useful when it is unknown how many different components might need a piece of data (e.g., multiple user interfaces). Also, components do not get bogged down with repeated requests for information from many different sources. Publish–subscribe protocols are often more difficult to debug because the syntax of the message is often hidden in a simple string type. Thus problems are not revealed until runtime when a component tries, and fails, to parse an incoming message. Publish–subscribe protocols are also not as readable when it comes to sending commands from one module to another. Instead of calling an explicit method or function with parameters, a command is issued by publishing a message with the command and parameters in it and then having that message be parsed by a subscriber. Finally, publish–subscribe protocols often use a single central server to dispatch messages to all subscribers, providing a single point of failure and potential bottleneck.

JAUS

Recently, a standard has emerged in the defense robotics community not only for a communication protocol but also for definitions of messages that are sent via that communication protocol. The joint architecture for unmanned systems (JAUS) defines a set of reusable messages and interfaces that can be used to command autonomous systems [12.64–66]. These reusable components reduce the cost of integrating new hardware components into autonomous systems. Reuse also allows for components developed for one autonomous system to be used by another autonomous system. JAUS has two components: a *domain model* and a *reference*

architecture. The domain model is a representation of the unmanned systems' functions and information. It contains a description of the system's functional and informational capabilities. The former includes models of the system's maneuvering, navigational, sensing, payload, and manipulation capabilities. The latter includes models of the system's internal data, such as maps and system status. The reference architecture provides a well-defined set of messages. Messages cause actions to commence, information to be exchanged, and events to occur. Everything that occurs in a **JAUS** system is precipitated by messages. This strategy makes **JAUS** a component-based, message-passing architecture.

The **JAUS** reference architecture defines a system hierarchy, as shown in Fig. 12.7. The topology defines the *system* as the collection of vehicles, operator control units (**OCUs**), and infrastructure necessary to provide the full robotic capability. Subsystems are individual units (e.g., vehicles or **OCUs**) in the system. Nodes define a distinct processing capability within the architecture and route **JAUS** messages to components. Components provide the different execution capabilities and respond directly to command messages. Components might be sensors (e.g., a SICK laser or a vision sensor), actuators (a manipulator or a mobile base) or payloads (weapons or task sensors). The topology (the layout of particular system, subsystems, nodes, and components) is defined by the system implementers based on task requirements.

At the core of **JAUS** is a set of well-defined messages. **JAUS** supports the following message types.

- **Command**: Initiate mode changes or actions
- **Query**: Used to solicit information from a component
- **Inform**: Response to a query
- **Event set up**: Passes parameters to set up an event
- **Event notification**: Sent when the event happens

JAUS has about 30 predefined messages that can be used to control robots. There are messages for con-

trol of a robotic vehicle. For example, the *global vector driver* message performs closed-loop control of the desired global heading, altitude, and speed of a mobile vehicle. There are also sensor messages such as *global pose sensor*, which distributes the global position and orientation of the vehicle. There are also manipulation messages in **JAUS**. For example, the *set joint positions* message sets the desired joint position values. The *set tool point* message specifies the coordinates of the end-effector tool point in terms of the coordinate system attached to the end-effector.

JAUS also has user-definable messages. Messages have headers that follow a specific format and include message type, destination address (e.g., system, subsystem, node, and component), priority, etc. While **JAUS** is primarily point to point, **JAUS** messages can also be marked as *broadcast* and distributed to all components. **JAUS** also defines coordinate systems for navigation and manipulation to ensure all components understand any coordinates sent to them.

12.3.2 Behavioral Control

Behavioral control represents the lowest level of control in a robot architecture. It directly connects sensors and actuators. While these are typically hand-crafted functions written in C or C++, there have been specialized languages developed for behavioral control, including ALFA [12.67], Behavioral Language [12.68], and Rex [12.69]. It is at this level that traditional control theory (e.g., proportional–integral–derivative (**PID**) functions, Kalman filters, etc.) resides. In architectures such as 3T, the behavioral layer functions as a *Brookian machine* – that is, the layer is composed of a small number of behaviors (also called skills) that perceive the environment and carry out the actions of the robot.

Example

Consider an office delivery robot that operates in a typical office building. The behavioral control layer con-

Fig. 12.7 The **JAUS** reference architecture topology (after **JAUS** Reference Architecture document [12.64])

tains the control functions necessary to move around in the building and carry out delivery tasks. Assuming the robot has an a priori map of the building, some possible behaviors for this robot include:

1. Move to location while avoiding obstacles
2. Move down hallway while avoiding obstacles
3. Find a door
4. Find a door knob
5. Grasp a door knob
6. Turn a door knob
7. Go through door
8. Determine location
9. Find office number
10. Announce delivery.

Each of these behaviors ties sensors (vision, range sensing, etc.) to actuators (wheel motors, manipulator motors, etc.) in a tight loop. In architectures such as Subsumption, all behaviors are running concurrently with a hierarchical control scheme inhibiting the outputs of certain behaviors. In AuRA [12.30], behaviors are combined using potential functions. Other architectures [12.25, 69] use explicit *arbitration* mechanisms to choose amongst potentially conflicting behaviors.

In architectures such as 3T [12.37], not all of the behaviors are active at the same time. Typically, only a few behaviors that do not conflict would be active at a time (e.g., behaviors 2 and 9 in the example above). The executive layer (Sect. 12.3.3) is responsible for activating and deactivating behaviors to achieve higher-level tasks and to avoid conflicts between two behaviors competing for the same resource (e.g., an actuator).

Situated Behaviors

An important aspect of these behaviors is that they be *situated*. This means that the behavior works only in very specific situations. For example, behavior 2 above moves down a hallway, but this is appropriate only when the robot is situated in a hallway. Similarly, behavior 5, which grasps a door knob, is appropriate only when the robot is within grasping distance of a door knob. The behavior is not responsible for putting the robot in the particular situation. However, it should recognize that the situation is not appropriate and signal as such.

Cognizant Failure

A key requirement for behaviors is that they know when they are not working. This is called *cognizant failure* [12.70]. For example, behavior 5 in our example (grasping the door knob) should not continually grasp at air if it is failing. More succinctly, the behavior should not continue to *bang its head against the wall*. A common problem with early Subsumption robots is that the

behaviors did not know they were failing and continued to take actions that were not resulting in progress. It is not the job of the behavioral control layer to decide what to do in a failure situation; it is only necessary to announce that the behavior has failed and halt activity.

Implementation Constraints

The behavioral control layer is designed to bring the speed and reactivity of Subsumption to robot control. For this reason, the behaviors in the behavioral control layer need to follow the philosophies of Subsumption. In particular, the algorithms used for behaviors should be constant in state and time complexity. There should be little or no search at the behavioral control level, and little iteration. Behaviors should simply be transfer functions that take in signals (from sensors or other behaviors) and send out signals (to actuators or other behaviors), and repeat these several times a second. This will allow for reactivity to changing environments. More controversial is how much state should be allowed at the behavioral level. Brooks famously said several years ago to *use the world as its own best model* [12.68] – that is, instead of maintaining internal models of the world and querying those models, the robot should instead directly sense the world to get its data. State such as maps, models, etc. belong at the higher levels of the three-tiered prototype architecture, not at the behavioral control layer. Certain exceptions, such as maintaining state for data filtering calculations, could be made on a case-by-case basis. Gat [12.71] argues that any state kept at the behavioral layer should be ephemeral and limited.

12.3.3 Executive

The executive layer is the interface between the numerical behavioral control and the symbolic planning layers. The executive is responsible for translating high-level plans into low-level behaviors, invoking behaviors at the appropriate times, monitoring execution, and handling exceptions. Some executives also allocate and monitor resource usage, although that functionality is more commonly performed by the planning layer.

Example

Continuing the example of an office delivery robot, the main high-level task would be to deliver mail to a given office. The executive would decompose this task into a set of subtasks. It may use a geometric path planner to determine the sequence of corridors to move down and intersections at which to turn. If there are doorways along the route, a task would be inserted to open and pass through the door. At the last corridor, the executive would add a concurrent task that looks for the

office number. The final subtasks would be to announce that the person has mail and to concurrently monitor whether the mail has been picked up. If it is not picked up after some period of time, an exception would be triggered that invokes some recovery action (perhaps announcing again, perhaps checking to make sure the robot is at the correct office, perhaps notifying the planning layer to reschedule the delivery for a later time).

Capabilities

The example above illustrates many of the capabilities of the executive layer. First, the executive decomposes high-level tasks (goals) into low-level tasks (behaviors). This is typically done in a *procedural* fashion: the knowledge encoded in the executive describes *how* to achieve tasks, rather than describing *what* needs to be done and having the executive figure out the *how* by itself. Sometimes, though, the executive may also use specialized planning techniques, such as the route planner used in the example above. The decomposition is typically a hierarchical *task tree* (Fig. 12.8), with the leaves of the task tree being invocations and parameterizations of behaviors.

Besides decomposing tasks into subtasks, executives add and maintain temporal constraints between tasks (usually between sibling tasks only, but some executive languages permit temporal constraints between any pair of tasks). The most common constraints are *serial* and *concurrent*, but most executives support more expressive constraint languages, such as having one task begin 10 s after another one starts or having one task end when another ends.

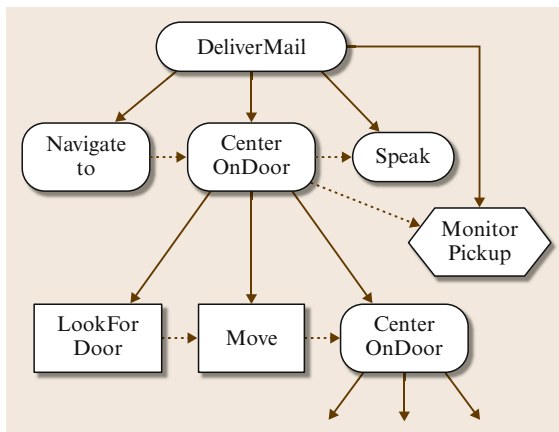

Fig. 12.8 Hierarchical task tree for mail-delivery task (lozenge nodes are interior; rectangular nodes are leaves; hexagonal node is an execution monitor; solid arrows are parent-child relationships; dashed arrows are sequential constraints)

The executive is responsible for dispatching tasks when their temporal constraints are satisfied. In some executives, tasks may also specify resources (e.g., the robot's motors or camera) that must be available before the task can be dispatched. As with behaviors, arbitrating between conflicting tasks can be a problem. In the case of executives, however, this arbitration is typically either programmed in explicitly (e.g., a rule that says what to do in cases where the robot's attempt to avoid obstacles takes it off the preferred route) or handled using priorities (e.g., recharging is more important than mail delivery).

The final two important executive capabilities are execution monitoring and error recovery. One may wonder why these capabilities are needed if the underlying behaviors are reliable. There are two reasons. First, as described in Sect. 12.3.2, the behaviors are situated, and the situation may change unexpectedly. For instance, a behavior may be implemented assuming that a person is available to pick up the mail, but that may not always be the case. Second, in trying to achieve some goal, the behavior may move the robot into a state that is unexpected by the executive. For instance, people may take advantage of the robot's obstacle avoidance behavior to *herd* it into a closet. While the behavior layer may, in fact, keep the robot safe in such situations, the executive needs to detect the situation in order to get the robot back on track.

Typically, execution monitoring is implemented as a concurrent task that either analyzes sensor data directly or activates a behavior that sends a signal to the executive when the monitored situation arises. These correspond to *polling* and *interrupt-driven* monitors, respectively.

Executives support various responses to monitors being triggered. A monitor may spawn subtasks that handle the situation, it may terminate already spawned subtasks, it may cause the parent task to fail, or it may raise an exception. The latter two responses involve the *error recovery* (also called *exception handling*) capability. Many executives have tasks return status values (success or failure) and allow parent tasks to execute conditionally based on the return values. Other executives use a hierarchical exception mechanism that throws named exceptions to ancestor nodes in the task tree. The closest task that has registered a handler for that exception tries to handle it; if it cannot, it rethrows the exception up the tree. This mechanism, which is inspired by the exception handling mechanisms of C++, Java, and Lisp, is strictly more expressive than the return-value mechanism, but it is also much more difficult to design systems using that approach, due to the non-local nature of the control flow.

Implementation Constraints

The underlying formalism for most executives is a hierarchical finite-state controller. Petri nets [12.72] are a popular choice for representing executive functions. In addition, various languages have been developed specifically to assist programmers in implementing executive-level capabilities. We briefly discuss aspects of several of these languages: reactive action packages (RAPs) [12.4, 31], the procedural reasoning system (PRS) [12.43, 44], the execution support language (ESL) [12.12], the task description language (TDL) [12.56], and the plan execution interchange language (PLEXIL) [12.13].

These languages all share features and exhibit differences. One distinction is whether the language is stand-alone (RAPs, PRS, PLEXIL) or an extension of an existing language (ESL is an extension of Common Lisp; TDL is an extension of C++). Stand-alone languages are typically easier to analyze and verify, but extensions are more flexible, especially with respect to integration with legacy software. While stand-alone executive languages all support interfaces to user-defined functions. These interfaces are usually limited in capability (such as what types of data structures can be passed around).

All of these executive languages provide support for hierarchical decomposition of tasks into subtasks. All except PLEXIL allow for recursive invocation of tasks. RAPs, TDL, and PLEXIL have syntax that distinguishes leaf nodes of the task tree/graph from interior nodes.

All these languages provide capabilities for expressing conditionals and iteration, although with RAPs and PLEXIL these are not core-language constructs, but must be expressed as combinations of other constructs. Except for TDL, the languages all provide explicit support for encoding pre- and post-conditions of the tasks and for specifying success criteria. With TDL, these concepts must be programmed in, using more primitive constructs. The stand-alone languages all enable local variables to be defined within a task description, but provide for only limited computation with those variables. Obviously, with extension languages the full capability of the base language is available for defining tasks.

All the languages support the simple serial (sequential) and concurrent (parallel) temporal constraints between tasks, as well as timeouts that can be specified to trigger after waiting a specified amount of time. In addition, TDL directly supports a wide range of temporal constraints – one can specify constraints between the start and end times of tasks (e.g., *task B starts after task A starts* or *task C ends after task D starts*) as well as metric constraints (e.g., *task B starts 10 seconds after*

task A ends or *task C starts at 1pm*). ESL and PLEXIL support the signaling of events (e.g., when tasks transition to new states) that can be used to implement similarly expressive types of constraints. In addition, ESL and TDL support task termination based on the occurrence of events (e.g., *task B terminates when task A starts*).

The languages presented differ considerably in how they deal with execution monitoring and exception handling. ESL and TDL both provide explicit execution monitoring constructs and support exceptions that are *thrown* and then *caught* by registered handlers in a hierarchical fashion. This type of exception handling is similar to that used in C++, Java, and Lisp. ESL and TDL also support *clean-up* procedures that can be invoked when tasks are terminated. RAPs and PLEXIL use return values to signal failure, and do not have hierarchical exception handling. PLEXIL, though, does support clean up procedures that are run when tasks fail. PRS has support for execution monitoring, but not exception handling. ESL and PRS support the notion of *resources* that can be shared. Both provide support for automatically preventing contention amongst tasks for the resources. In the other executive languages, this must be implemented separately (although there are plans to extend PLEXIL in this area).

Finally, RAPs, PRS and ESL all include a symbolic database (*world model*) that connects either directly to sensors or to the behavior layer to maintain synchrony with the real world. Queries to the database are used to determine the truth of preconditions, to determine which methods are applicable, etc. PLEXIL has the concept of a *lookup* that performs a similar function, although it is transparent to the task how this is implemented (e.g., by a database lookup or by invoking a behavior-level function). TDL leaves it up to the programmer to specify how the tasks connect to the world.

12.3.4 Planning

The planning component of our prototype layered architecture is responsible for determining the long-range activities of the robot based on high-level goals. Where the behavioral control component is concerned with the here-and-now and the executive is concerned with what has just happened and what should happen next, the planning component looks towards the future. In our running example of an office delivery robot, the planning component would look at the day's deliveries, the resources of the robot, and a map, and determine the optimal delivery routes and schedule, including when the robot should recharge. The planning component is also responsible for replanning when the situation changes.

For example, if an office is locked, the planning component would determine a new delivery schedule that puts that office's delivery later in the day.

Types of Planning

Chapter 9 describes approaches to robot planning in detail. Here, we summarize issues with respect to different types of planners as they relate to layered architectures.

The two most common approaches used are hierarchical task net (HTN) planners and planner/schedulers. HTN planners [12.73, 74] decompose tasks into subtasks, in a manner similar to what many executives do. The main differences are that HTN planners typically operate at higher levels of abstraction, take resource utilization into account, and have methods for dealing with conflicts between tasks (e.g., tasks needing the same resources, or one task negating a precondition needed by another task). The knowledge needed by HTN planners is typically fairly easy to specify, since one indicates directly *how* tasks are to be achieved.

Planner/schedulers [12.75, 76] are useful in domains where time and resources are limited. They create high-level plans that schedule when tasks should occur, but typically leave it to the executive to determine exactly how to achieve the tasks. Planner/schedulers typically work by laying out tasks on time lines, with separate time lines for the various resources that are available on the robot (motors, power, communication, etc.). The knowledge needed by planner/schedulers includes the goals that tasks achieve, the resources they need, their duration, and any constraints between tasks.

Many architectures provide for specialized planning *experts* that are capable of solving particular problems efficiently. In particular, these include motion planners, such as path planners and trajectory planners. Sometimes, the planning layer of the architecture invokes these specialized planners directly; in other architectural styles, the motion planners are part of the lower levels of the architecture (the executive, or even the behavioral layer). Where to put these specialized planners is often a question of style and performance (Sect. 12.5).

Additionally, some architectures provide for multiple planning layers [12.40, 45, 77]. Often, there is a *mission* planning layer at the very top that plans at a very abstract level, over relatively long periods of time. This layer is responsible mainly for selecting which high-level goals are to be achieved over the next period of time (and, in some cases, determining in which order to achieve them) in order to maximize some objective function (e.g., net reward). The lower *task* planning layer is then responsible for determining exactly how and when to achieve each goal. This break-

down is usually done for efficiency reasons, since it is difficult to plan simultaneously at both a detailed level and over a long time horizon.

Integrating Planning and Execution

There are two main approaches to the integration of the planning and execution components in robotic architectures. The first approach is that the planning component is invoked as needed by the executive and returns a plan. The planning component is then dormant until called again. Architectures such as ATLANTIS [12.71] and Remote Agent [12.45] use this approach, which requires that the executive either leave enough time for planning to complete or that it *saves* the system until planning is complete. In the Remote Agent, for instance, a special *planning* task is explicitly scheduled.

The second approach is that the planning component sends high-level tasks down to the executive as required and monitors the progress of those tasks. If tasks fail, replanning is done immediately. In this approach, the planning component is always running and always planning and replanning. Signals must pass in real time between the planner and the executive to keep them synchronized. Architectures such as 3T [12.37] use this second approach. The first approach is useful when the system is relatively static, so that planning can occur infrequently, at relatively predictable times. The second approach is more suited to dynamic environments, where replanning is more frequent and less predictable.

Other decisions that need to be made when integrating planning and execution are when to stop task decomposition, where to monitor plan execution, and how to handle exceptions. By planning all the way down to primitive actions/behaviors, the planner has a very good notion of what will happen during execution, but at a price of much more computation. Also, some task decompositions are easier to describe procedurally (using an executive language) rather than declaratively (using a planning language). Similarly, monitoring at the executive level tends to be more efficient, since the monitoring happens closer to the robot sensors, but the planner may be able to use its more global knowledge to detect exceptions earlier and/or more accurately. With respect to handling exceptions, executives can handle many on their own, at the price of breaking the expectations used by the planner in scheduling tasks. On the other hand, having exceptions handled by the planner typically involves replanning, which can be computationally expensive.

For all these integration issues, however, a middle ground usually exists. For instance, one can choose to decompose some tasks more deeply than others, or han-

dle certain exceptions in the executive and others in the planner. In general, the *right* approach usually involves

a compromise and is determined by analyzing the domain in detail (Sect. 12.5).

12.4 Case Study – GRACE

In this section, we present the architecture of a fairly complex autonomous mobile robot. Graduate robot attending conference (GRACE) resulted from the efforts of five research institutions (Carnegie Mellon, Naval Research Laboratory, Northwestern University, Metrica, and Swarthmore College) to tackle the American Association for Artificial Intelligence (AAAI) Robot Challenge. The Challenge was for a robot to attend the AAAI National Conference on Artificial Intelligence as a participant – the robot must find the registration desk (without knowing the layout of the convention center beforehand), register for the conference, and then, after being provided with a map, find its way to a given location in time to give a technical talk about itself.

The architectural design of the robot was particularly important given the complexity of the task and the need to integrate techniques that had been previously developed by the five institutions. These techniques included localization in a dynamic environment, safe navigation in the presence of moving people, path planning, dynamic replanning, visual tracking of people, signs and landmarks, gesture and face recognition, speech recognition and natural language understanding, speech generation, knowledge representation, and social interaction with people.

GRACE is built on top of an real world interface (RWI) B21 base and has an expressive computer-animated face projected on a flat-panel liquid-crystal display (LCD) screen (Fig. 12.9). Sensors that come with the B21 include touch, infrared, and sonar sensors.

Fig. 12.9 The robot GRACE

Near the base is a SICK scanning laser range finder that provides a 180° field of view. In addition, GRACE has several cameras, including a stereo camera head on a pan-tilt unit (PTU) built by Metrica TRAC Labs and a single-color camera with pan-tilt-zoom capability, built by Canon. GRACE can speak using a high-quality speech-generation software (Festival), and receive speech responses using a wireless microphone headset (a Shure TC computer wireless transmitter/receiver pair).

The behavioral layer of the architecture consisted of individual processes that controlled particular pieces of hardware. These programs provided abstract interfaces to either control the hardware or return information from sensors. To accommodate the different coding styles of the various groups involved, both synchronous, blocking and asynchronous, nonblocking calls were supported by most of the interfaces (for the nonblocking calls, the interfaces allowed programmers to specify a callback function to be invoked when data was returned). Interfaces at the behavioral level included robot motion and localization (this interface also provided laser information), speech recognition, speech generation, facial animation, color vision, and stereo vision (Fig. 12.10).

The architecture used individual processes for each of the behavioral capabilities, mainly because the underlying code had been developed by different organizations. While having a large number of processes run concurrently is somewhat inefficient, trying to integrate everything into a monolithic process was thought to be too difficult. In addition, the use of separate processes facilitated development and debugging, since one needed to run only those aspects of the system that were being tested.

The executive layer consisted of separate programs for achieving each subtask of the challenge – finding the registration desk, riding the elevator, standing in line, interacting with the person at the desk, navigating to the talk, and giving the talk (Fig. 12.10). As is common in many implemented robotic systems, the GRACE architecture did not have a planning layer – since the high-level plan was fixed and relatively straightforward, it was coded explicitly. Several of the executive-layer programs were written using TDL (Sect. 12.3.3), which facilitated concurrent control and monitoring of the various tasks.

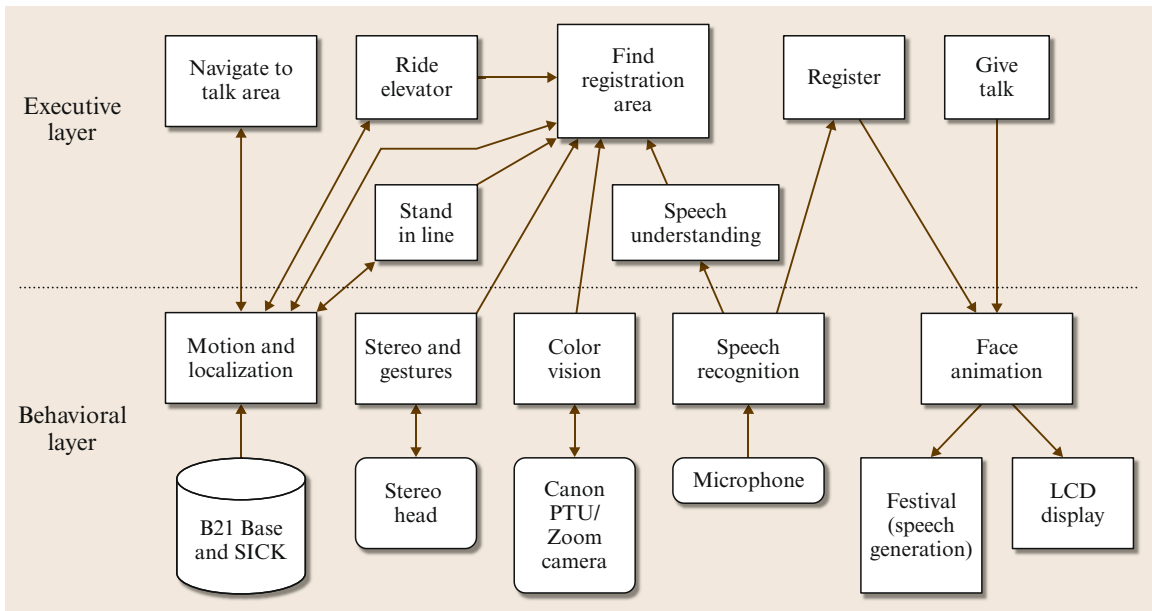

Fig. 12.10 GRACE's architectural structure

One particularly involved task was finding the registration desk (recall that GRACE had no idea where the booth was, or even what the convention center looked like). TDL was used to create a finite-state machine that allowed GRACE to maintain multiple goals, such as using an elevator to get to a particular floor and following directions to find the elevator (Fig. 12.11). The top-level goal was to find the registration desk. Intermediate sub-goals were created as GRACE interacted with people to determine the directions to the desk. If there were no directions to follow, GRACE performed a random walk until a person was detected using its laser scanner. GRACE then engaged in conversation with the person to obtain directions. GRACE could handle simple commands, such as *turn left* and *go forward five meters*, as well as higher-level instructions, such as *take the elevator* and *turn left at the next intersection*. In addition, GRACE could ask questions, such as *am I at the registration desk?* and *is this the elevator?* The TDL-based finite-state machine was used to determine which interactions were appropriate at various times and to prevent the robot from getting confused.

Communication between processes used the interprocess communication (IPC) messaging package [12.9, 78]. IPC supports both publish–subscribe and client–server messaging, and enables complex data structures to be passed transparently between processes. One side benefit of using IPC to communicate between processes was the ability to log all message traffic (both message name and data content). This proved invaluable, at times, in determining why the system failed

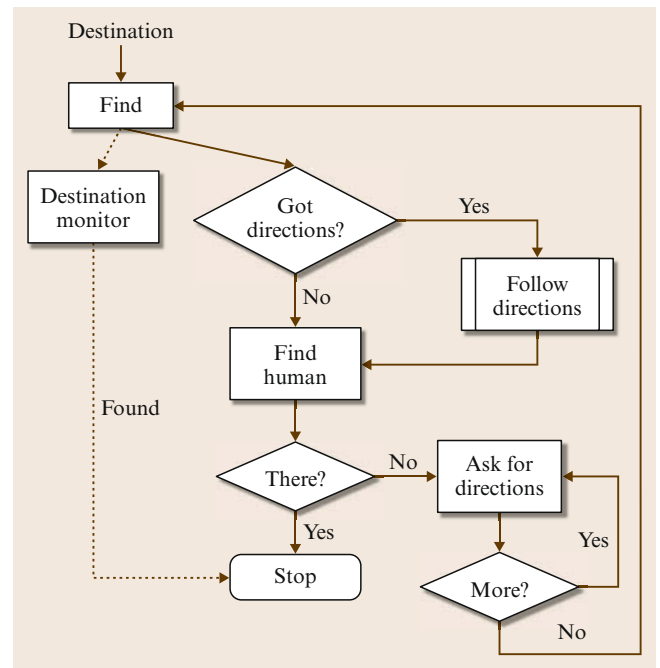

Fig. 12.11 Finite-state machine for GRACE's task for following directions to the registration booth

to act as expected – did a process send out a message with invalid data? Did it fail to send out a message in a timely fashion? Was the receiving process blocked, for some reason? Was there a timing issue? While wading through the message traffic was often tedious, in

some cases it was the only way to catch intermittent bugs.

In July 2002, **GRACE** successfully completed the challenge at the Shaw Convention Centre in Edmonton, Canada. The processes at the behavioral level generally worked as anticipated – this was largely attributed to the fact that those modules were ported from previously developed (and hence well-tested) systems. While generally functional, the executive-level processes had

more problems with off-nominal situations. This is largely attributed to problems in sensor interpretation, as well as mistaken assumptions about what the convention center was going to look like (for instance, it turned out that some of the barriers were made of glass, which is largely invisible to the laser). Overall, however, the architecture itself worked as expected, enabling a large body of complex software to be integrated rather quickly and operate together effectively.

12.5 The Art of Robot Architectures

Designing a robot architecture is much more of an art than a science. The goal of an architecture is to make programming a robot easier, safer, and more flexible. Thus, the decisions made by a developer of a robot architecture are influenced by their own prior experiences (e.g., what programming languages they are familiar with), their robot and its environment, and the tasks that need to be performed. The choice of a robot architecture should not be taken lightly, as it is the authors' experiences that early architectural decisions often persist for years. Changing robot architectures is a difficult proposition and can set back progress while a great deal of code is reimplemented.

The art of designing a robotic architecture starts with a set of questions that the designer needs to ask. These questions include:

- What are the tasks the robot will be performing? Are they long-term tasks? Short-term? User-initiated? Robot-initiated? Are the tasks repetitive or different across time?
- What actions are necessary to perform the tasks? How are those actions represented? How are those actions coordinated? How fast do actions need to be selected/changed? At what speed do each of the actions need to run in order to keep the robot safe?
- What data is necessary to do the tasks? How will the robot obtain that data from the environment or from the users? What sensors will produce the data? What representations will be used for the data? What processes will abstract the sensory data into representations internal to the architecture? How often does the data need to be updated? How often can it be updated?
- What computational capabilities will the robot have? What data will these computational capabilities produce? What data will they consume? How will the computational capabilities of a robot be divided, structured, and interconnected? What is the best decomposition/granularity of computa-

tional capabilities? How much does each computational capability have to know about the other capabilities? Are there legacy computational capabilities (from other robots, other robot projects, etc.) that will be used? Where will the different computational capabilities reside (e.g., onboard or offboard)?

- Who are the robot's users? What will they command the robot to do? What information will they want to see from the robot? What understanding do they need of the robot's computational capabilities? How will the user know what the robot is doing? Is the user interaction peer to peer, supervisory, or as a bystander?
- How will the robot be evaluated? What are the success criteria? What are the failure modes? What is the mitigation for those failure modes?
- Will the robot architecture be used for more than one set of tasks? For more than one kind of robot? By more than one team of developers?

Once designers have answers to all (or most) of these questions, they can then begin building some *use cases* for the types of operations they want the robot to perform and how they want users to interact with it. These use cases should specify the outward behavior of the robot with respect to its environment and its users. From the use cases, an initial partitioning of robot functionality can be developed. This partitioning should be accompanied by a *sequence diagram* that shows the transfer of information and control over time amongst the various components of the robot architecture [12.79]. After this, a more formal specification of the interfaces between architectural components can be developed. This may be done using a language such as the interface definition language (IDL) of **CORBA** or by defining the messages to be distributed in a publish-subscribe protocol. This is an important step, as once implementation begins it is very costly to change interfaces. If an interface does change, all stakeholders need

to be notified and need to agree to the change. The most common integration problems in robot architectures are mismatches between what components expect and what they are receiving in the way of data.

An advantage of tiered architectures with clear interface definitions is that the different layers can be developed in parallel. The behavioral control layer can be implemented and tested on the robot using a human as an executive. The executive can be implemented and tested using state machine *stubs* for the expected behaviors on the robot. The planning layer can be implemented and tested using *stubs* for the tasks in the executive. The *stubs* merely acknowledge that they

were called and report back appropriately. Then, the tiers can be integrated to test timing and other runtime issues. This parallel approach speeds up the development of a robot architecture, but is possible only if the roles and interfaces between components are clearly defined and respected. There is still considerable real-time debugging necessary during integration. In our experiences, most of the development time in robot architectures is still spent on the behavioral control layer – that is, sensing and acting are still the hard parts of robot control, as compared to execution and planning. Having a good, robust behavioral control layer goes a long way towards having a competent robot architecture.

12.6 Implementing Robotic Systems Architectures

Robot System Architectures offer a coarse-grain view of the structure of a robot system, which is modelled according to the functional decomposition (or composition) of parts. Unfortunately, there are concerns that cannot be effectively described and modularised using the concept of composition of high cohesion functional modules. Such concerns relate to the software systems as a whole hence crosscutting their modular structure. Non-functional requirements such as real-time performance, fault tolerance, and safety, are typical examples of properties that emerge from multiple parts of a system and cannot be confined into individual modules. In order to meet these requirements, software development efforts are mainly focused on delivering highly efficient implementations of control applications that exploit at best the capabilities of specific hardware platforms to perform a specific set of tasks in specific operational environments.

The race towards performance and the pressure to develop proof-of-concept code to test a new theory [12.80] push robotic engineers to neglect other quality attributes of a software system, such as maintainability, interoperability, and reusability. As a result, a huge corpus of software applications, which implement the entire spectrum of robot functionality, algorithms, and control paradigms, is potentially available in robotic research laboratories as open source libraries. Unfortunately, they are often not reusable even in slightly different application scenarios, because the assumptions and constraints about the computational and robotics hardware, and the software and operational environments are hidden and hard coded in the software implementation.

A large variety of today's robotic systems is designed according to the relatively small number of robot control architecture paradigms discussed in the

previous sections. Nevertheless, the software that implements their control applications differs significantly from system to system. These differences relate, for example, to the data structures defined to store relevant information (e.g., the map of the environment, the robot kinematic model), the application programming interfaces (APIs) to drive sensors and actuators [12.81], the information model used to represent key concepts (e.g., geometric relations and coordinate representations). These differences indicate that the most common robot functionalities have been re-implemented from scratch innumerable times.

During the last few years, many ideas from software engineering (such as component-based development and model-driven engineering) have been progressively introduced in the construction of robotic software systems to simplify their development and improve their quality (see [12.82] for a survey).

Modern robot control systems are typically designed as (logically) distributed component-based systems [12.83, 84]. Here, components are units of implementation and represent a code-based way of considering the system. As an analogy, in the electronics domain re-usable off-the-shelf electronic components have been available for many years in the form of integrated chips (ICs) which can be bought and deployed in other parts of the world. This is possible because each IC packages a clear set of functionality and provides a well-defined external interface.

In Robot System Architectures the interactions between software components are usually more complex compared to more traditional business applications. In Robotics, the software developer faces the complexity of event-based, reactive, and distributed interactions between sensors and motors and between several processing algorithms. Managing concurrent access to shared

resources by multiple (distributed) activities is one of the main issues, as thoroughly discussed in [12.85]. For this reason, robotic-specific component-based frameworks and toolkits have been developed, which offer mechanisms for real-time execution, synchronous and asynchronous communication, data flow and control flow management, and system configuration.

The following section reviews some of the most recent approaches and frameworks that have been specifically defined for robotics.

12.6.1 Agile Robot Development Network (aRDnet)

aRDnet [12.86] is a software suite developed at the German Aerospace Center (DLR) Institute of Robotics and Mechatronics that supports the development of distributed component-based systems for complex mechatronic systems with hard real-time requirements. The aRDnet suite has been used to implement computationally demanding control loops in the kHz range running over all the 41 degrees of freedom (DOF) of the upper humanoid body Justin, such as impedance control and collision avoidance. The robot control system is structured as a network of functional blocks and communication links distributed over a network of computers connected by a fast digital bus like the Gigabit-Ethernet.

An aRDnet functional block is a software module with multiple input and output ports that hide the actual transportation protocol, i.e., user datagram protocol (UDP) sockets or EtherCAT to exchange data with interconnected blocks. Blocks can be executed by individual processes or can be grouped in synchronization groups (e.g., for blocks interfacing the robot hardware) executed iteratively by a single process according to the *synchronous data flow* model of computation. Different synchronization groups can interact asynchronously through non blocking read and write operations.

12.6.2 Yet Another Robot Platform (YARP)

YARP [12.87] is an open-source project developed at the LIRA-Lab of the University of Genova in collaboration with MIT Computer Science and Artificial Intelligence Laboratory (CSAIL). It has been conceived with the same objectives as aRDnet, i.e., the development of distributed control systems for high DOF robots, such as the humanoid bodies. It consists in a lightweight software library for concurrent and distributed programming that has been used and tested on several operating systems.

Similarly to aRDnet, distributed software modules exchange data through input/output asynchronous

communication ports. Differently from aRDnet, **YARP** ports can manage multiple connections for a given module at different data rates according to different protocols (e.g., transfer control protocol (TCP), UDP, multicast) allowing for the configuration of the quality of service (QOS) of the inter-module communication: an output port can send data to many destinations, while an input port can receive data from multiple connections.

12.6.3 Open Robot Control Software (OROCOS)

Orocos is one of the oldest open source framework in robotics, under development since 2001, and with professional industrial applications and products using it since about 2005 [12.88]. The focus of Orocos has always been to provide a hard real-time capable component framework, the so-called Real-Time Toolkit (RTT) implemented in C++ and as independent as possible from any communication middleware and operating system. Similarly to aRDnet and **YARP**, components interact with each other by exchanging data and events asynchronously through lock-free input/output ports according to the Data Flow communication paradigm.

The distinguish feature of **OROCOS** is the definition of a component model that specifies a standard behaviour for concurrent activities. Components with real-time, deterministic and cyclic behaviour get fixed and cyclic time budgets for computation and within a computation cycle they must reach stable intermediate states. **OROCOS** components are implemented as extension (inheritance) of the base class TaskContext, have their own thread of execution, and can be deployed as objects that share the same address space or as executables that communicate using the **CORBA** middleware.

12.6.4 Smartsoft

Smartsoft [12.89] is an open source framework that specifically addresses issues related to communication among software components of a robotic control system. Similarly to **OROCOS**, it defines a port-based component model, whose distinguished feature is a rich set of standard component interfaces (called communication patterns) with strictly defined interaction semantics:

- **Send:** Defines one-way communication with a client/server relationship
- **Query:** Two-way request communication with a client/server relationship

- *Push newest/push timed*: 1-to-n distribution (broadcast) with a publisher/subscriber relationship
- *Event*: Asynchronous conditioned notification with a client/server relationship
- *Dynamic wiring*: Dynamic component wiring with a master/slave relationship.

Smartsoft is one of the first open source frameworks that has developed an open source toolchain for robotic software development based on the Eclipse Modeling Project. The toolchain implements a workflow that guides the software developer from high level design of the robot system architecture down to the components implementation and deployment through automatic model-to-model transformations.

12.6.5 Robot Operating System (ROS)

ROS [12.90] is a message-based peer-to-peer communication infrastructure supporting the easy integration of independently developed software components, called ROS nodes. A ROS system is thus a computation graph consisting of a set of nodes communicating with one another. Nodes are blocks of functional code and are implemented as classes that wrap robotic software libraries and provide access to the communication mechanisms of the underlying infrastructure (the ROS core). Nodes are organized into packages (file system folders containing libraries, nodes, and message definitions), which are grouped into thematic stacks (i.e., the navigation stack). Messages are typed data structures that can be nested into compound messages and are exchanged between nodes according to the publish/subscribe communication paradigm in an asynchronous manner without the need for the interacting nodes to know each other and to participate to the interaction at the same time. Messages are organized by topics, which correspond to information subjects that allow subscribers to recognize the events they are interested in. When a node receives a message belonging to a subscribed topic, a message handler is invoked asynchronously, which performs some computation on the message payload data and possibly generates a new message of a given topic to publish the computation results.

The distinguish characteristics of ROS is the lack of enforced architecture in ROS libraries, i.e., ROS nodes are designed as individually reusable components. An application is built by configuring individual nodes in such a way that they can exchange messages belonging to common topics. This characteristic

favours the decentralized development of many small packages by experts in the various robotics sub-domains.

12.6.6 GenoM/BIP

GenoM [12.91] is a component-oriented software package developed by the LAAS CNRS robotics group that is used for specifying and implementing the functional level of robot system architectures. GenoM components are collections of control services, which execute a finite state automaton and are implemented by a set of C functions called codels, which get appropriately called during specific state transitions (i.e., start, exec, error, etc.). GenoM components exchange data and events through posters that are regions of shared memory.

The distinguish feature of the GenoM component model is the integration with the Behavior-Interaction-Priorities (BIPs) framework. BIP is a software framework and toolset for formally modeling and verifying complex, real-time component-based systems to guarantee correctness-by-construction of robotic control systems. BIP is used to produce a formal interaction model, which can be used for system level coordination to run (using the BIP engine) the functional layer composed of all the GenoM modules. BIP allows the hierarchical construction of compound components by using connectors, which interconnect the ports of GenoM components and models two basic modes of communication, namely, caller/provider and broadcaster/listener.

12.6.7 Best Practice in Robotics (BRICS)

Complementary to the projects described above BRICS [12.92], a joint research project funded by the European Commission, has formalized the robot development process according to the principles of Model Driven Engineering [12.93] and has provided tools, models, and functional libraries, which allow reducing the development time of robot software systems.

In particular, the concepts of Component Framework and Software Product Line have been introduced in the robot development process [12.94, 95] as illustrated in  VIDEO 273. This approach promotes the routine use of existing software or software knowledge to construct new software, so that similarities in requirements, architectures and design between applications can be exploited to achieve substantial benefits in software quality, productivity, and business performance.

12.7 Conclusions and Further Reading

Robot architectures are designed to facilitate the concurrent execution of task-achieving behaviors. They enable systems to control actuators, interpret sensors, plan, monitor execution, and deal with unexpected contingencies and opportunities. They provide the conceptual framework within which domain-dependent software development can take place, and they often provide programming tools that facilitate that development.

While no single architecture has proven to be best for all applications, researchers have developed a variety of approaches that can be applied in different situations. While there is not yet a specific formula for determining which architecture will be best suited for a given application, this chapter provides some

guidelines to help developers in selecting the right architecture for the job. That being said, layered architectures have proven to be increasingly popular, due to their flexibility and ability to operate at multiple levels of abstraction simultaneously.

The book *Kortenkamp et al.* [12.96] provide several chapters on architectures that have influenced this chapter. Most text books in robotics [12.20, 97, 98] have sections on robot architectures. For many years in the mid 1990s, the AAAI Spring Symposia on Artificial Intelligence had sessions devoted to robot architectures, although proceedings from those symposia are not widely available. More information on GRACE can be found in [12.99–101].

François Michaud, Monica Nicolescu

Nature is filled with examples of autonomous creatures capable of dealing with the diversity, unpredictability, and rapidly changing conditions of the real world. Such creatures must make decisions and take actions based on incomplete perception, time constraints, limited knowledge about the world, cognition, reasoning and physical capabilities, in uncontrolled conditions and with very limited cues about the intent of others. Consequently, one way of evaluating intelligence is based on the creature's ability to make the most of what it has available to handle the complexities of the real world. The main objective of this chapter is to explain *behavior-based systems* and their use in autonomous control problems and applications. The chapter is organized as follows. Section 13.1 overviews robot control, introducing behavior-based systems in relation to other established approaches to robot control. Section 13.2 follows by outlining the basic principles of behavior-based systems that make them distinct from other types of robot control architectures. The concept of basis behaviors, the means of modularizing behavior-based systems, is presented in Sect. 13.3. Section 13.4 describes how behaviors are used as building blocks for creating representations for use by behavior-based systems, enabling the robot to reason about the world and about itself in that world. Section 13.5 presents several different classes of learning methods for behavior-based systems, validated on single-robot and multi-robot systems. Section 13.6 provides an overview of various robotics problems and application domains that have successfully been addressed or

are currently being studied with behavior-based control. Finally, Sect. 13.7 concludes the chapter.

13.1 Robot Control Approaches

Situated robotics deals with embodied machines in complex, challenging, often dynamically changing environments. *Situatedness* thus refers to existing in a complex, challenging environment, and having one's behavior strongly affected by it. In contrast, robots that exist in static, unchanging environments are usually not thought to be situated. These include assembly robots operating in complex but highly structured, fixed, and strongly predictable environments, specifically engineered and controlled to enable the robot to accomplish very specific tasks. The predictability and stability of the environment have a direct impact on the complexity of the robot that must operate in it; situated robots therefore present a significant challenge for the designer.

Robot control, also referred to as robot decision-making or robot computational architecture, is the process of taking information about the environment through the robot's sensors, processing it as necessary in order to make decisions about how to act, and executing actions in the environment. The complexity of the environment, i. e., the level of situatedness, has a direct impact on the complexity of control, which is, in turn, directly related to the robot's task. Control architectures are covered in Chap. 12 of the Handbook.

While there are infinitely many possible ways to program a robot, there are fundamentally four classes of robot control methods, described below.

13.1.1 Deliberative – Think, Then Act

In deliberative control, the robot uses all of the available sensory information, and all of the internally stored knowledge, to reason about what actions to take next. The control system is usually organized using a functional decomposition of the decision-making processes, consisting of a sensory processing module, a modeling module, a planning module, a value judgment module, and an execution module [13.1]. Such functional decomposition allows complex operations to be performed, but implies strong sequential interdependencies between the decision-making modules.

Reasoning in deliberative systems is typically in the form of planning, requiring a search of possible state–action sequences and their outcomes. *Planning*, a major component of artificial intelligence, is known to be a computationally complex process. The process requires the robot to perform a sequence of sense–plan–act steps (e.g., *combine the sensory data into a map of the world, then use the planner to find a path in the map, then send steps of the plan to the robot's wheels*) [13.2–4]. The robot must construct and then potentially evaluate all possible plans until it finds one that

enables it to reach its goal, solve the task, or decide on a trajectory to execute. Shakey, an early mobile robot that used STRIPS, a general planner, is an example of such a system applied to the problem of avoiding obstacles and navigating based on vision data [13.5].

Planning requires the existence of an internal, symbolic representation of the world, which allows the robot to look ahead into the future and predict the outcomes of possible actions in various states, so as to generate plans. The internal model, thus, must be kept accurate and up to date. When there is sufficient time to generate a plan and the world model is accurate, this approach allows the robot to act strategically, selecting the best course of action for a given situation. However, being situated in a noisy, dynamic world usually makes this impossible [13.6, 7]. Today, no situated robots are purely deliberative. The advent of alternative architectures was driven by the need for faster yet appropriate action in response to the demands of complex and dynamically changing real-world environments.

13.1.2 Reactive – Don't Think, (Re)Act

Reactive control is a technique for tightly coupling sensory inputs and effector outputs, typically involving no intervening reasoning [13.8] to allow the robot to respond very quickly to changing and unstructured environments [13.9]. Reactive control is inspired by the biological notion of *stimulus–response*; it does not require the acquisition or maintenance of world models, as it does not rely on the types of complex reasoning processes utilized in deliberative control. Rather, rule-based methods involving a minimal amount of computation, and no internal representations or knowledge of the world are typically used. Reactive systems achieve rapid real-time responses by embedding the robot's controller in a collection of preprogrammed, concurrent condition–action rules with minimal internal state (e.g., *if bumped, stop; if stopped, back up*) [13.8, 10]. This makes reactive control especially well suited to dynamic and unstructured worlds where having access to a world model is not a realistic option. Furthermore, the minimal amount of computation involved means that reactive systems are able to respond in a timely manner to rapidly changing environments.

Reactive control is a powerful and effective control method that abounds in nature; insects, which vastly outnumber vertebrates, are largely reactive. However, limitations to pure reactivity include the inability to store (much if any) information or have memory or internal representations of the world [13.11], and therefore the inability to learn and improve over time.

Reactive control trades off complexity of reasoning for fast reaction time. Formal analysis has shown that, for environments and tasks that can be characterized a priori, reactive controllers can be very powerful, and if properly structured, capable of optimal performance in particular classes of problems [13.12, 13]. In other types of environments and tasks where internal models, memory, and learning are required, reactive control is not sufficient.

13.1.3 Hybrid – Think and Act Concurrently

Hybrid control aims to combine the best aspects of reactive and deliberative control: the real-time response of reactivity and the rationality and optimality of deliberation. As a result, hybrid control systems contain two different components, the reactive/concurrent condition–action rules and the deliberative ones, which must interact in order to produce a coherent output. This is challenging because the reactive component deals with the robot’s immediate needs, such as moving while avoiding obstacles, and thus operates on a very fast time scale and uses direct external sensory data and signals. In contrast, the deliberative component uses highly abstracted, symbolic, internal representations of the world, and operates on them on a longer time scale, for example to perform global path planning or plan for high-level decision-making. As long as the outputs of the two components are not in conflict, the system requires no further coordination. However, the two parts of the system must interact if they are to benefit from each other. Consequently, the reactive system must override the deliberative one if the world presents some unexpected and immediate challenge. Analogously, the deliberative component must inform the reactive one in order to guide the robot toward more efficient and optimal trajectories and goals. The interaction of the two parts of the system requires an intermediate component, which reconciles the different representations used by the other two and any conflicts between their outputs. The construction of this intermediate component is typically the greatest challenge of hybrid system design.

Hybrid systems are referred to as layered, or tiered, robot control architecture (Chap. 12). Many are referred to as *three-layer architectures* because of their structure, which consists of the reactive (execution) layer, intermediate (coordination) layer, and deliberative (organization/planning) layer. The layers are organized according to the principle of increasing precision of control in the lower layers with decreasing intelligence [13.14]. A great deal of research has been invested into the design these components and their interactions [13.2, 15–21].

Three-layer architectures aim to harness the best of reactive control in the form of dynamic, concurrent and time-responsive control, and the best of deliberative control, in the form of globally efficient actions over a long time scale. However, there are complex issues involved in interfacing these fundamentally differing components, and the manner in which their functionality should be partitioned is not yet well understood [13.22].

13.1.4 Behavior-Based Control – Think the Way You Act

Behavior-based control employs a set of distributed, interacting modules, called *behaviors*, that collectively achieve the desired system-level behavior. To an external observer, behaviors are patterns of the robot’s activity emerging from interactions between the robot and its environment. To a programmer, behaviors are control modules that cluster sets of constraints in order to achieve and maintain a goal [13.22, 23]. Each behavior receives inputs from sensors and/or other behaviors in the system, and provides outputs to the robot’s actuators or to other behaviors. Thus, a behavior-based controller is a structured network of interacting behaviors, with no centralized world representation or focus of control. Instead, individual behaviors and networks of behaviors maintain any state information and models.

Well-designed behavior-based systems take advantage of the dynamics of interaction among the behaviors themselves, and between the behaviors and the environment. The functionality of behavior-based systems can be said to emerge from those interactions and is thus neither a property of the robot or the environment in isolation, but rather a result of the interplay between them [13.22]. Unlike reactive control, which utilizes collections of reactive rules with little if any state and no representation, behavior-based control utilizes collections of behaviors, which have no such constraints: behaviors do have state and can be used to construct representations, thereby enabling reasoning, planning, and learning.

13.1.5 When to Use What

Characterizing a given robot computational architecture based on these four classes of control is often a matter of degree, as architectures attempt to combine the advantages of these paradigms, especially the responsiveness, robustness, and flexibility of the behavior-based approach with the use of abstract representational knowledge for reasoning and planning about the world [13.22] or for managing multiple

conflicting goals. For example, **AuRA** (autonomous robot architecture) uses a planner to select behaviors [13.22] and 3T uses behaviors in the execution layer of a three-level hierarchical architecture [13.24]; both of these architectures dynamically reconfigure behaviors according to reasoning based on available world knowledge [13.22]. Goller et al. [13.25] use a set of 15 navigational behaviors with 17 activating behaviors, combined with a task planner and a topological navigation module.

Each of the above approaches to robot control has its strengths and weaknesses, and all play important and successful roles in certain robot control problems and applications. Each offers interesting but different insights, and no single approach should be seen as ideal or otherwise in the absolute. Rather, the choice of robot control methodology should be based on the particular task, environment, and robot. Robot control presents fundamental tradeoffs having to do with time scale of response, system organization, and modularity: thinking allows looking ahead to avoid mistakes, but only as long as sufficient, accurate, up-to-date information is available, otherwise reacting may be the best way to handle the world. As a consequence of these inherent tradeoffs, it is important to have different methodologies at our disposal rather than having to fit all controller needs into a single methodology. Selecting an appropriate control methodology and designing an architecture within it is best determined by the sit-

uatedness properties of the problem, the nature of the task, the level of efficiency or optimality needed, and the capabilities of the robot, both in terms of hardware, world modeling, and computation.

For example, reactive control is the best choice for environments demanding immediate response, but such speed of reaction comes at the price of being myopic, not looking into the past or the future. Reactive systems are also a popular choice in highly stochastic environments, and environments that can be properly characterized so as to be encoded in a reactive input–output mapping. Deliberative systems, on the other hand, are the only choice for domains that require a great deal of strategy and optimization, and in turn search and planning. Such domains, however, are not typical of situated robotics, but more so of scheduling, game playing, and system configuration, among others. Hybrid systems are well suited for environments and tasks where internal models and planning are needed, and the real-time demands are few, or sufficiently independent of the higher-level reasoning.

Behavior-based systems, in contrast, are best suited for environments with significant dynamic changes, where fast response and adaptivity are crucial, but the ability to do some looking ahead and avoid past mistakes is required. Those capabilities are spread over the active behaviors, using representations if necessary [13.23], as discussed in the following.

13.2 Basic Principles of Behavior-Based Systems

Behavior-based robotics was developed for situated robots, allowing them to adapt to the dynamics of real-world environments without operating upon abstract representations of reality [13.11], but also giving them more computational capability and expressivity than are available to reactive robots. Behavior-based systems maintain a tight coupling of sensing and action through behaviors, and use the behavior structure for representation and learning. Therefore, it is uncommon for a behavior to perform extensive computation or reasoning relying on a traditional world model, unless such computation can be done in a timely manner in response to dynamic and fast-changing environment and task demands.

Figure 13.1 summarizes the general components of low-level behavior-based systems. Note that there is a distinction between *activation conditions*, which allow the behavior to generate actions, and *stimuli*, from which actions are generated.

The basic principles of behavior-based control can be summarized briefly as follows:

- Behaviors are implemented as control laws (sometimes similar to those used in control theory), either in software or hardware, as a processing element or as a procedure.
- Each behavior can take inputs from the robot's sensors (e.g., proximity sensors, range detectors, contact sensors, camera) and/or from other modules in the system, and can send outputs to the robot's effectors (e.g., wheels, grippers, arm, speech) and/or to other modules.
- Many different behaviors may independently receive input from the same sensors and output action commands to the same actuators.
- Behaviors are encoded to be relatively simple, and are added to the system incrementally.
- Behaviors (or subsets thereof) are executed concurrently, not sequentially, in order to exploit par-

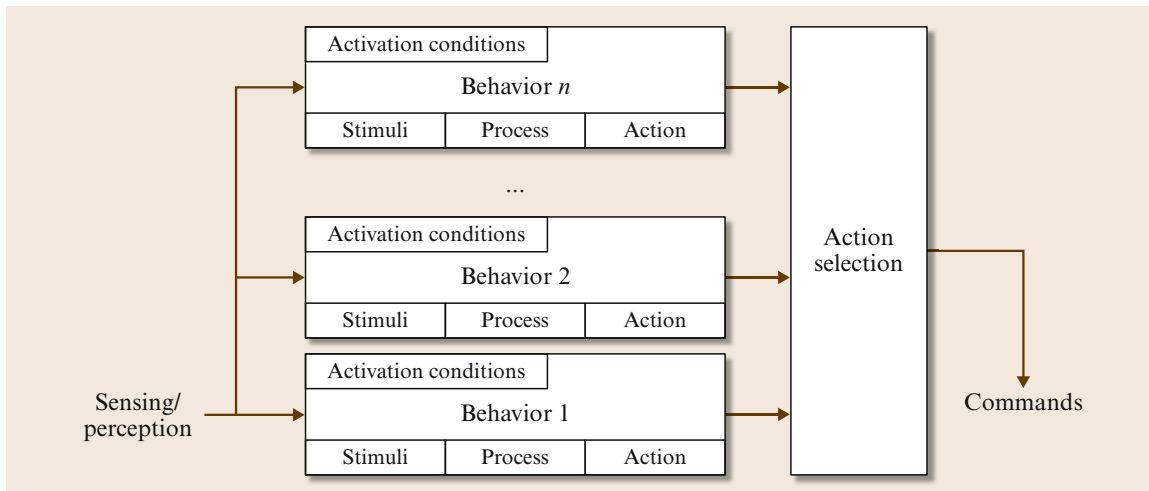

Fig. 13.1 A general schematic of one type of behavior-based systems

allelism and speed of computation, as well as the interaction dynamics among behaviors and between behaviors and the environment.

Behaviors are designed at a variety of abstraction levels, facilitating bottom-up construction of behavior-based systems. New behaviors are introduced into the system incrementally, from the simple to the more complex, until their interaction results in the desired overall capabilities of the robot. In general, behaviors encode time-extended processes, not atomic actions that are typical of feedback control (e.g., *go-forward-by-a-small-increment* or *turn-by-a-small-angle*). The interaction and integration of temporal and spatial effects are of key importance in behavior-based systems. Merely having one process controlling an actuator for predetermined intervals of time, or using as many processes as there are effectors to control them, does not suffice as the basis for behavior-based control. It is the combined effect of concurrent processes over time and driven by perception and internal states that creates the relevant behavior-based dynamics in a control system.

As a first step, survival behaviors, such as *collision-avoidance*, are implemented. These behaviors are often reactive in nature, since reactive rules can and often do form components of simple behaviors. Next, behaviors are added that provide more complex capabilities, such as *wall-following*, *target-chasing*, *homing*, *find-object*, *get-recharged*, *avoid-the-light*, *aggregate-with-group*, *pick-up-object*, *find-landmark*. Depending on the system being designed, behaviors implementing distributed representations may be added, as may be behaviors capable of learning about the world and/or the robot itself, and operating on those

representations and learned information. Representation and learning are addressed in more detail in Sect. 13.4.

Behavior-based systems are typically designed so the effects of the behaviors interact largely in the environment rather than internally through the system, taking advantage of the richness of the interaction dynamics by exploiting the properties of situatedness. These dynamics are sometimes called *emergent* behaviors because they *emerge* from the interactions and are not internally specified by the robot's program. Therefore, the internal behavior structure of a behavior-based system need not necessarily mirror its externally manifested behavior. For example, a robot that flocks with other robots may not have a specific *flocking* behavior; instead, its interaction with the environment and other robots may result in flocking, although its only behaviors may be *avoid-collisions*, *stay-close-to-the-group*, and *keep-going*.

For such an approach to work, a behavior-based system must resolve the issue of choosing a particular action or behavior from multiple options, a process known as *action selection* [13.26] (or also *behavior coordination* [13.27], *behavior selection* [13.28], or *behavior fusion* [13.29]) problem. This is one of the central design challenges of behavior-based systems. One approach to action selection is the use of a predefined behavior hierarchy, in which commands from the highest-ranking active behavior are sent to the actuator and all others are ignored. Numerous approaches based on other principles as well as ad hoc methods for addressing the action selection problem have been developed and demonstrated on robotic systems. These methods aim to provide increased flexibility but, in some cases, may do so at the cost of reducing the ef-

iciency or the analyzability of the resulting control systems. Developed methods include varieties of motor schemas [13.16], command fusion [13.30], spreading of activation through a behavior network [13.31, 32], behavior auctions [13.33, 34], and fuzzy logic [13.35, 36], among many others. *Pirjanian* [13.27] presents a survey of action selection mechanisms. Some frameworks also support the use of several action selection mechanisms, such as APOC [13.28] (allowing dynamic selection and changes) and iB2C [13.29] (along with development guidelines, analysis tools and visualization techniques).

13.2.1 Misconceptions

Because behavior-based systems are not always simple to describe or implement, they are also often misunderstood. The most common misconception equates reactive and behavior-based systems. Historically, the advent of behavior-based systems was inspired by reactive systems; both maintain real-time couplings between sensing and action [13.18, 37], and are structured and developed bottom-up, consisting of distributed modules. However, behavior-based systems are fundamentally *more powerful* than reactive systems, because they can store representations [13.38], while reactive systems cannot. Reactive systems are limited by their lack of internal state; they are incapable of using internal representations and learning. Behavior-based systems overcome this limitation because their underlying unit of representation, the *behavior*, can store state internally, in a distributed fashion.

The means by which state and representation are distributed in behavior-based systems is one of the sources of the flexibility of the control methodology. Representations in behavior-based systems are distributed, so as to best match and utilize the underlying behavior structure that causes the robot to act. This is how *thinking* can be organized in much the same way as *acting*. Thus if a robot needs to plan ahead, it does so in a network of communicating behaviors, rather than a single centralized planner. If a robot needs to store a large map, the map might be distributed over multiple behavior modules representing its components, such as a network of landmarks, as in [13.39], or a network of parameterized navigation behaviors, as in [13.40, 41], so that reasoning about the map/environment/task can be done in an active fashion, through using message passing within the behavior network. The planning and reasoning components of the behavior-based system use the same mechanisms as the sensing- and action-oriented behaviors, and as a result do not op-

erate on a fundamentally different time scale and representation relative to one another. Various forms of distributed representations are used, ranging from static table structures and networks, to active procedural processes implemented within the behavior networks.

Another area of common misconception relates to the comparison between behavior-based systems and hybrid systems. Because the two use such different modularization strategies, it is often assumed that one approach (usually hybrid) has improved expressive capabilities. In fact, behavior-based and hybrid systems have the same expressive and computational capabilities: both can exploit representations and look ahead, but they do so in very different ways. This has resulted in different application domains being best suited to behavior-based versus hybrid systems. Specifically, hybrid systems dominate the domain of single-robot control, unless the task is so time-demanding that a reactive system must be used. Behavior-based systems dominate the domain of multi-robot control because the notion of collections of behaviors within the system scales well to collections of such robots, resulting in robust, adaptive group behavior [13.42, 43]. See Chap. 53 on multiple mobile robot systems for more details.

Like hybrid systems, behavior-based systems may be organized in layers, but unlike hybrid systems, the layers do not differ from each other drastically in terms of organization, time scale or representation used. Behavior-based systems typically do not employ the hierarchical/sequential division favored by hybrid approaches. Behavior-based systems do provide both low-level control and high-level deliberation; the latter can be performed by one or more distributed representations that compute(s) over the other behaviors or modules, often directly utilizing low-level behaviors and their outputs. The resulting systems, built from the bottom-up, do not divide into differently represented and independent components, and consist of elements directly tied in some ways to behaviors. The power, elegance, and complexity of behavior-based systems all stem from the ways in which their constituent behaviors are designed, coordinated, and used. For instance, monitoring how behaviors for low-level control contribute to the commands issued over time can be used to evaluate how appropriate the robot operates in its environment based on its set of activated behaviors. Different methods can be used to implement such a mechanism, such as temporal analyses [13.36, 44–47], pattern recognition techniques [13.48] and graph-based representations [13.49–51].

Therefore, the principles to keep in mind when extending behavior-based to higher decisional levels are:

1. Use behaviors as the building block of both decision-making and action execution processes;
2. Use distributed parallel evaluation and concurrent control over lower-level behaviors, which take real-time inputs from sensory data and send real-time commands to effectors;
3. Have no centralized components, each module carrying out its own responsibilities.

The following sections describe and illustrate in more detail how behavior-based principles can be used to control robots.

13.3 Basis Behaviors

The process of designing a set of behaviors for a robot is referred to as *behavior synthesis*, and is typically performed by hand, although some methods for automated synthesis behaviors have been developed and successfully demonstrated [13.52, 53]. In all cases, behaviors perform a particular activity, attain a goal, or maintain some state. The notion of defining an *optimal* behavior set for a given robot or task has been considered, but it is generally accepted that such a notion is not realistic as it is dependent on too many specifics of a given system and environment that cannot currently be effectively formalized.

Matarić et al. [13.43, 54] describe *basis behaviors*, also referred to as *primitive behaviors*, as a tool for structuring and thus simplifying behavior synthesis. Basis behaviors are a set of behaviors such that each is *necessary*, in the sense that each either achieves, or helps to achieve, a relevant goal that cannot be achieved without it by other members of that set. Furthermore, the basis behavior set is *sufficient* for achieving the goals mandated for the controller. The term *basis* was chosen to be indicative of the similar notion within linear algebra. The prop-

erty of necessity or parsimony is analogous to the idea of linear independence; the idea of sufficiency is similar to the linear algebraic concept of span. Basis behaviors should be simple, stable, robust, and scalable.

Another organizational principle of basis behaviors is *orthogonality*. Two behaviors are orthogonal if they do not interfere with one another, each inducing no side-effects in the other. This is often achieved by having behaviors take mutually exclusive sensory inputs. Another method is to have different behaviors control separate effectors. This form of factorization is only feasible when the robot's dynamics do not inhibit their separability. In contrast, autonomous helicopter control is an example of a highly coupled system; Saripalli et al. [13.55] demonstrated how behavior-based control can be effectively applied to robust autonomous helicopter flight.

Basis behavior design principles have been applied to single-robot as well as multi-robot behavior-based systems in a variety of applications, ranging from navigation to foraging, coordinated group movement, box pushing, and others.

13.4 Representation in Behavior-Based Systems

Embedding representation into behavior-based systems involves the challenge of conserving the basic principles of the approach at all levels of system decision-making. Combining abstract reasoning processes with behaviors must be done in a way that exploits interaction dynamics and desirable emergent system properties.

Matarić et al. [13.38, 56] describe work with a robot named *Toto* and as shown by  VIDEO 35, which introduced the use of distributed representation into behavior-based systems. Toto's capabilities included safe navigation, landmark detection, map learning, and path planning in the learned map representation, all within the behavior-based framework. To exploit the principles underlying behavior-based control, Toto's representation was not a centralized map. Instead, any

newly discovered landmark in the environment was assigned to a new map representation behavior, which stored the landmark descriptor (type, estimated Cartesian location, and compass orientation). Whenever sensory inputs matched the landmark descriptor, the robot localized to that particular landmark and the behavior became active. The following is pseudo-code for each landmark behavior:

Algorithm 13.1

```

my-behavior-type: C
my-compass-direction: 0
my-approximate-location: (x,y)
my-approximate-length: 6.5
whenever received (input)

```

```

if input(behavior-type) = my-behavior-type
  and
    input(compass-direction) =
      my-compass-direction then
    active := true
  end if

```

As new landmarks are discovered, they are added to the map representation behavior network. In this way, the topology of the resulting map network is isomorphic to the topology of the network graph in the physical environment Toto has explored. The edges in the network graph are also communication links in the behavior network, allowing landmark behaviors to communicate through local message passing. Consequently, a currently active map behavior can send a message to its topological neighbor(s), thereby indicating expectation of it being the next recognized landmark and facilitating Toto's localization. Planning in the network takes place through the use of the same message-passing mechanism. The goal landmark (which could be selected by the user as part of the task, such as *go to this particular corridor or go to the nearest north-facing wall*), sends messages (i.e., spreads activation) from itself to its neighbors, which pass it on throughout the network. As messages are passed, the length of each landmark in the graph is accrued, thereby estimating the length of each path. The shortest path arriving at the currently active network behavior indicates the best direction to pursue toward the goal. This is equivalent to a distributed Di-

jkstra search. Importantly, because this search is an active ongoing process within a behavior map rather than a static process (as it would be in a centralized map representation), if the robot is picked up and moved to another location, as soon as it localizes, it continues on the optimal path to the goal: each landmark makes a local decision as to where to go next toward the goal, and no unique global path is stored in any central location/representation. Thus, the path is constantly refreshed and updated; if any route is blocked, the link in the graph is disconnected and the shortest path is updated dynamically.

Toto exemplifies how, in a behavior-based system, a representation can be stored in a distributed fashion, so as to best match the underlying behavior structure that produces the robot's external goal-driven activity. If Toto needs to make high-level decisions (such as planning ahead to a distant goal), it does so in a network of communicating behaviors, rather than a single centralized component. This results in scalable and efficient computation for the system as a whole, since the typically slower decision-making processes such as planning are distributed and modularized in a way that makes them more consistent with the time scale and representation of the rest of the system. Note the fundamental difference between this general attempt of behavior-based systems to homogenize their representation through the use of behaviors as universal modules, compared to hybrid systems which rely on inherently different representations and time scales at different levels of the system.

13.5 Learning in Behavior-Based Systems

The ability to improve performance over time and to reason about the world, in the context of a changing and dynamic environment, are important areas of research in situated robotics. Unlike in classical machine learning where the goal is typically to optimize performance over a long period of time, in situated learning the aim is to adapt relatively quickly toward attaining efficiency in the light of uncertainty. Models from biology are often considered, given its properties of learning directly from environmental feedback. Variations and adaptations of machine learning, and in particular reinforcement learning, have been effectively applied to behavior-based robots, which have demonstrated learning to walk [13.57], communicate [13.58], navigate and create topological maps [13.38, 59], divide tasks [13.23, 60], behave socially [13.61], and even identify opponents and score goals in robot soccer [13.62]. Methods from artificial life, evolutionary

computation/genetic algorithms, fuzzy logic, vision and learning, multi-agent systems, and many other research areas continue to be actively explored and applied to behavior-based robots as their role in animal modeling and practical applications continue to develop.

When operating in unpredictable and partially observable environments, an autonomous robot must examine the evolution of its general states, and try to capture what emerges from the interaction dynamics with its environment. Temporal integration of different types of observations is an important aspect of that capability [13.63, 64]. Work on motivational systems [13.47, 65–68] has shown that a balance between planning and reactivity for goal management can be achieved using internal variables activated or inhibited by different factors [13.42, 46, 69, 70]. Motivations can be cyclic (e.g., circadian rhythms) or change in various temporally dependent ways [13.68]. In general, the

notion of motivations is used to efficiently balance the need to adapt to the contingencies of the world and to accomplish the robot's goals.

In the following subsections, we discuss four successfully validated classes of learning approaches in behavior-based systems. The approaches differ in what is learned and where learning algorithms are applied, but in all cases behaviors are used as the underlying building blocks for the learning process.

13.5.1 Reinforcement Learning in Behavior-Based Systems

Behaviors are recognized as excellent substrates for speeding up reinforcement learning (RL), which is known to suffer from the curse of dimensionality. The earliest examples of RL in behavior-based systems demonstrated hexapod walking [13.57] and box-pushing [13.71]. Both decomposed the control system into a small set of behaviors, and used generalized input states, thereby effectively reducing the size of the state space. In the box-pushing example, the learning problem was broken up into modularized policies for learning separate mutually exclusive behaviors: for getting out when stuck, for finding the box when lost and not stuck, and for pushing the box when in contact with one and not stuck. The modularization into behaviors resulted in greatly accelerated as well as more robust learning. More recently, Kober et al. [13.72] demonstrated the use of reinforcement learning to learn a set of meta-parameters that enable the adaptation of learned motor plans, such as a table tennis pass or a dart throwing task, to new situations.

Scaling up reinforcement learning to multi-robot behavior-based systems has also been explored [13.23, 73]. In multi-robot systems, the environment presents further challenges of nonstationarity and credit assignment, due to the presence of other agents and concurrent learners. The problem was studied in the context of a foraging task with four robots, each initially equipped with a small set of basis behaviors (*searching, homing, picking-up, dropping, following, avoiding*) and learning individual behavior selection policies, i.e., which behavior to execute under which conditions. Due to interference among concurrent learners, this problem could not be solved directly by standard RL. *Shaping*, a concept from psychology [13.74], was introduced; it was subsequently adopted in robot RL [13.75]. Shaping pushes the reward closer to the subgoals of the behavior, and thus encourages the learner to incrementally improve its behaviors by searching the behavior space more effectively. *Mataric* [13.73] introduced shaping through *progress estimators*, measures of progress toward the goal of a given behavior during its execution.

This form of reward shaping addresses two issues associated with delayed reward: behavior termination and fortuitous reward. Behavior termination is event-driven; the duration of any given behavior is determined by the interaction dynamics with the environment, and can vary greatly. Progress estimators provide a principled means for deciding when a behavior may be terminated even if its goal is not reached and an externally generated event has not occurred. Fortuitous reward refers to reward ascribed to a particular situation–behavior (or state–action) pair which is actually a result of previous behaviors/actions. It manifests as follows: previous behaviors lead the system near the goal, but some event induced a behavior switch, and subsequent achievement of the goal is ascribed most strongly to the final behavior, rather than the previous ones. Shaped reward in the form of progress estimators effectively eliminates this effect. Because it provides feedback during behavior execution, it rewards the previous beneficial behaviors more strongly than the final one, thus more appropriately assigning credit. This case therefore illustrates how reinforcement learning has been successfully applied to behavior-based robotics, in particular at the level of behavior selection. The learning process is accelerated by the behavior structure, which provides a higher-level representation of actions and time-extended dynamics.

13.5.2 Learning Behavior Networks

The modularization of behavior-based systems as networks of behaviors allows for learning to be applied at the network level as well. *Nicolescu* and *Mataric* [13.40, 41] developed the notion of *abstract behaviors*, which separate the activation conditions of a behavior from its output actions (so-called *primitive behaviors*, which share the same principles as basis behaviors described Sect. 13.3); this allows for a more general set of activation conditions to be associated with the primitive behaviors. While this is not necessary for any single task, it is what provides generality to the representation. An abstract behavior is a pairing of a given behavior's activation conditions (i.e., preconditions) and its effects (i.e., postconditions); the result is an abstract and general operator much like those used in classical deliberative systems (Fig. 13.2). Primitive behaviors, which typically consist of a small basis set, may involve one or an entire collection of sequential or concurrently executing behaviors.

Networks of such behaviors are then used to specify strategies or general *plans* in a way that merges the advantages of both abstract representations and behavior-based systems. The nodes in the networks are abstract behaviors, and the links between them repre-

sent precondition and postcondition dependencies. The task plan or strategy is represented as a network of such behaviors. As in any behavior-based system, when the conditions of a behavior are met, the behavior is activated. Analogously, when the conditions of an abstract behavior are met, the behavior activates one or more primitive behaviors which achieve the effects specified in its postconditions. The network topology at the abstract behavior level encodes any task-specific behavior sequences, freeing up the primitive behaviors to be reused for a variety of tasks. Thus, since abstract behavior networks are computationally lightweight, solutions for multiple tasks can be encoded within a single system and dynamically switched.

Nicolescu and Matarić [13.40, 41] introduced a means for automatically generating such networks offline as well as at runtime. The latter enables a learning robot to acquire task descriptions dynamically, while observing its environment, which can include other robots and/or a teacher. The methodology was validated on a mobile robot following a human and acquiring a representation of the human-demonstrated task by observing the activation of its own abstract behavior pre- and postconditions, thus resulting in a new abstract behavior network representing the demonstrated task [13.76]. The robot was able to acquire novel behavior sequences and combinations (i.e., concurrently executing behaviors), resulting in successful learning of tasks involving visiting various targets in particular order as shown in [VIDEO 27](#) and [VIDEO 28](#), picking up, transporting, and delivering objects as shown in [VIDEO 32](#) and [VIDEO 33](#), dealing with barriers, and maneuvering obstacle courses in specific ways as shown in [VIDEO 30](#) and [VIDEO 31](#).

This approach has been extended to learning of more general task representations, in which every goal

is achieved through a linear superposition (or fusion) of robot primitives, and sequencing across goals is achieved through arbitration [13.77]. In this work, controllers are built from two components: *behavior primitives* (BPs) and *fusion primitives* (FPs), which can be sequenced to form *behavior networks*. The *behavior primitives* perform a set of actions under given environmental conditions and are represented using a schema-based approach [13.78]. A *fusion primitive* encapsulates a set of multiple concurrently running primitive behaviors through linear combination of the motor commands, expressed as a vector in the robot's coordinate system. The FPs combine these vectors by weighting them and fusing them through vector addition. The method allows for learning of both the goals involved in the task (represented as the sequence of goal-achieving fusion primitives) and also of the particular ways in which the same goals can be achieved (captured in the behavior weights). Using this learning approach, a robot is capable of learning multiple navigation styles (such as staying on the center/left/right side of a corridor, preferences for turning left or right at T-junctions and particular styles of navigating around obstacles).

13.5.3 Learning from Demonstration in Behavior-Based Systems

Learning by demonstration has also been combined with behavior-based systems to produce one-shot learning and teaching mechanisms for robot control [13.40, 79]. Furthermore, this type of behavior-based architecture has been used to learn ship navigation strategies [13.80]; during a learning phase, an instructor selects behaviors for a ship to execute in order to reach a specific goal, and a subsequent offline stage then generates dependency links between the behaviors that it witnessed during the learning phase.

Another form of learning by demonstration has used probabilistic methods to select and combine multiple behaviors [13.81]. There, the problem of learning what behaviors to execute during autonomous navigation is treated as a state estimation problem. During a learning phase, the robot observes commands used by a teacher. A particle filter then fuses the control commands that were demonstrated by the teacher to estimate behavior activation. The method produces a robust controller that is well suited for dynamic environments.

Learning by demonstration has also been used in a case-base reasoning framework [13.82], to teach a 4-legged Aibo robot different low-level navigation behaviors, such as following a ball and reaching a target. The learned behaviors encapsulate the kinematics and dynamics of the robot's control through the instruction process, which would be more difficult to achieve if de-

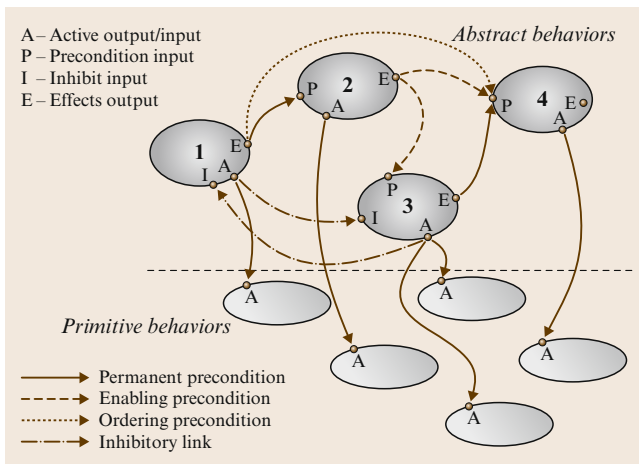

Fig. 13.2 Behavior network

signed by hand, and can successfully be combined into a newer, higher-level behavior, thus enabling hierarchical representations of robot tasks.

A method based on decision trees and Support Vector Machines has been used in [13.83] to find mappings between sensory data and patterns produced by behaviors in a learned feature space. The mapping allows a robot to identify behaviors shown by a human demonstrator and to further learn a sequential representation of the demonstrated task.

13.5.4 Learning from History of Behavior Use

Most deliberative approaches derive knowledge for reasoning about the world from sensor inputs and actions taken by the robot. This results in complex state-space representations of the world and does not take into consideration the context in which these sensations/actions are taken. As already discussed, behaviors, which are readily used as low-level control blocks driven by what is experienced from the interactions with the environment, can also serve as an abstract representation to model those interactions. One approach is to use history information [13.84], i. e., to explicitly take into consideration the time sequence of observations in order to make a decision. Applying this idea to behavior-based systems, by knowing the purpose of each of the behaviors and by observing their history of use, the robot can reason and ground its intentions in what it is experiencing in its operating environment. The concept of abstract behavior is exploited here as well, to activate behaviors and as a representation on which to learn.

Learning from history has been validated in behavior-based systems capable of making the robot change its behavior selection strategy for foraging colored objects (blocks) to a homing region in nonstationary, dynamically changing environments involving multiple concurrently learning robots [13.49–51]. In that foraging task, the robot is given two subtasks: search for a block (searching task), and bring it to the home region (homing task). The robot is given behaviors to accomplish these tasks: one behavior for the searching task, called *searching-block*, and two for the homing task, *homing* and *drop-block*. A *velocity control* behavior is also used in both of these tasks to make the robot move. All these behaviors are referred to as *task behaviors*. Conditions for activating task behaviors are preprogrammed based on the presence or absence of a block in front of the robot and the proximity of the home region.

The robot also needs to navigate safely in the environment. In this approach, an *avoidance* behavior is activated unless the robot is near home and carrying

a block; otherwise it is disabled to allow the robot to approach the home region. This type of behavior, used for handling harmful situations and interference while accomplishing a task, is referred to as a *maintenance behavior*. The designer determines the conditions in which maintenance behaviors should be used, but cannot indicate when they will occur during the task, as that is tied to the dynamics of the interaction between the robot and its environment.

The robot learns to use *alternative behaviors* (*follow-side*, *rest*, and *turn-randomly*), which introduce variety into its action repertoire by changing the way it accomplishes its tasks. In contrast to other types of behaviors, these have no a priori activation conditions; the objective is to allow the robot to learn when to activate these behaviors according to past experiences, for some preset periods of time, when it is experiencing interference in accomplishing its task. Figure 13.3 illustrates how the behaviors are prioritized using a fixed suppression mechanism, similar to the subsumption architecture [13.9] but with the difference that the activated behaviors, i. e., those allowed to issue outputs, change dynamically.

Following behavior-based principles, an activated behavior may or may not be used to control the robot,

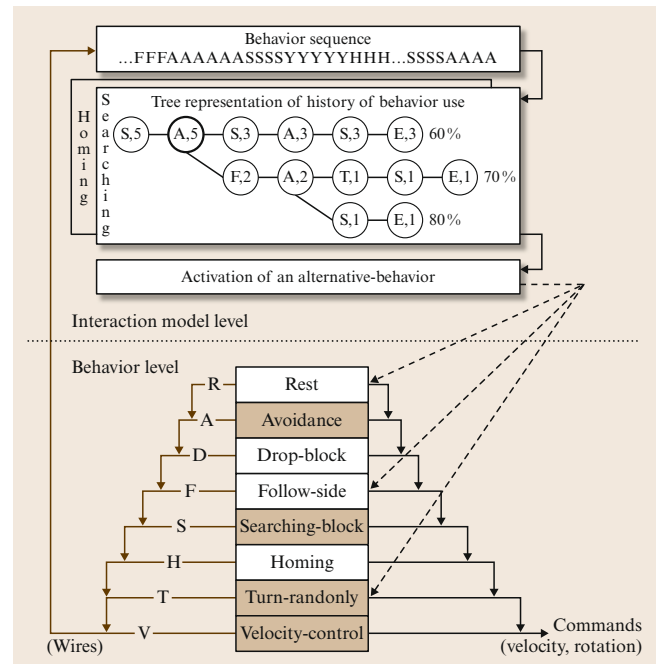

Fig. 13.3 Organization of the behavior level and the interaction model level. Behavior on *colored background* represent an example of activated behaviors for the searching task, with *Turn-randomly* as a chosen alternative behavior. For clarity, sensory inputs to behaviors are not shown

depending on the sensory conditions it monitors and the arbitration mechanism. An activated behavior is used only when it provides commands that actually control the robot. Whenever a behavior is used, its corresponding symbol is sent to the interaction model, generating the sequence of behaviors used over time. Separate learning trees are used for each task; determining which one to use is done based on the activated task behavior.

The algorithm uses a tree structure to store the history of behavior use. The upper part of Fig. 13.3 shows a typical tree with nodes storing the behavior (H for use by *homing* and *drop-block*) used for controlling the robot while accomplishing its task, and n , the number of times a transition between the node itself and its successor has been made (as observed from behavior use). Initially, the tree for a particular task is empty and is incrementally constructed as the robot goes about its task. Leaf nodes are labeled with E (for end-node) and store the total *performance* of the particular tree path. Whenever a path is completely reused, when the same sequence of behaviors is used, the E node is updated with the average of the stored and current performances for recent trials.

Learning is done through reinforcement. Depending on the domains and the tasks, a variety of factors can be used to evaluate performance, and different metrics can be used with this learning algorithm. To see how far the idea of self-evaluation and learning by observing behavior use can be taken, the evaluation function used here is not based on characteristics about the environment or the task. Instead, it is based on the amount of time behaviors are used. Comparison between the time spent using behaviors associated with the tasks and the time spent exploiting maintenance behaviors is used to derive the evaluation criterion. Consequently,

behavioral selection strategy is derived from what can be learned from the experiences of the robot in its environment, without having to characterize a priori what can be considered to be optimal operating conditions in the environment.

Using the tree and the evaluation function, the algorithm has two options for using a maintenance behavior:

1. Not to make any changes in its active behavior set (the *observe* option);
2. To activate an alternative behavior.

The sequence of nodes in a tree path characterizes the interactions experienced by the robot in the world. Different selection criteria can be used by comparing the performance at the current position in the tree with the expected performance, following an exploration (to learn the effects of alternative behaviors) then exploitation (to exploit what was learned in previous trials) strategy. The expected performance of a given node is the sum of the stored end-node performances in its subpaths, multiplied by the frequency of use of the subpaths relative to the current position in the tree. Finally, since this algorithm is used in noisy and nonstationary conditions, deleting paths is necessary to keep the interaction model up to date. This is done by keeping only a fixed number of the most recent paths in the tree.

Results obtained with this approach show that the robot is able to learn unanticipated strategies (like resting in front of a static obstacle to increase the turning angle when it starts to move again, making it locate a target) and original ones (like yielding when close to other robots or following walls when the center of the pen is crowded). Developing such capabilities is important in general, because it makes it possible for robots to learn in nonstationary environments, which are common in natural settings.

13.6 Applications and Continuing Work

Behavior-based robots have demonstrated various standard capabilities, including obstacle avoidance, navigation, terrain mapping, following, chasing/pursuit, object manipulation, task division and cooperation, and learning maps [13.85], navigation and walking. They have also demonstrated some novel applications like large-scale group behaviors including flocking, foraging, and soccer playing, human-robot interaction, and modeling insect [13.86] and even human behavior [13.87–89]. Behavior-based methods span mobile robots, shopping carts [13.25], underwater vehicles, planetary rovers for space exploration, assistive [13.90], interactive and social robots [13.91,92], as well as

snake-like modular robots [13.93], robots capable of grasping, manipulation, walking, running, and many others. Consumer market products, such as the iRobot Roomba Robotic Floorvac [13.94], also use behavior-based control, demonstrating its broad applicability.

The use of behavior-based architectures for robot control has evolved from single-system implementations to approaches that combine forms of learning, state estimation, and distributed computation. Behaviors have been combined with fuzzy inference systems for indoor navigation using mobile robots [13.35,36,95–97], where a command fusion module acts as an arbiter that combines multiple fuzzy behavior outputs

into a single control signal. This strategy ensures the robot is capable of making inferences in the face of uncertainty.

Behavior-based methods have been employed in multi-robot systems from the outset [13.43], as illustrated by  VIDEO 34, and are still used [13.98, 99]. Multi-robot researchers also consider tasks requiring tightly coupled cooperation; [13.100] for an overview and discussion. Such tasks typically require low-level sensor-sharing and/or for higher-level explicit coordination. Behavior-based controllers have been developed and extended in order to address these challenges. For example, *Parker et al.* [13.101] considered reusable behavior units that can be automatically redistributed for low-level information processing. *Werger and Matarić* [13.102] described broadcast of local eligibility (BLE) to enable higher-level group behaviors by allowing communications to influence each robot's local action selection mechanism. *Gerkey and Matarić* [13.103, 104] demonstrated scalable and efficient market-based coordination algorithms for multi-robot coordination in a variety of tasks, including tightly coupled ones (e.g., box-pushing [13.105]). A similar strategy was applied to a robot sensor network, which achieves concurrent, sequential and asynchronous multi-robot task allocation [13.106]. The market-based auction algorithm developed in this system uses a fitness function that enhances fault tolerance and the fairness of the task allocation process. *Sedat and Aydan* [13.107] use a fractal conductivity-based approach to generate movements of a coordinated team of mobile sensors. The team explores an environment to reach a target that is a source of a potential field chemical substance contaminated into sea or lake water.

Several researchers have shown that behavior-based controllers allow for sophisticated coordination through a utility-centered model of the collective task. Behaviors use this representation to produce actions that consider each robot's impact on the performance of the group as a whole. *Iocchi et al.* [13.108] have shown this in heterogeneous multi-robot system, while *Batalin and Sukhatme* [13.109] demonstrated that complex, interrelated and dynamic tasks can be performed in coordinated ways in robots with behavior-based controllers interacting with a sensor network. *Stroupe and Balch* [13.110] considered a mapping task and developed move value estimation for robot teams (MVERT), essentially a behavior-based method for maximizing group knowledge.

Because behavior-based methods lend itself naturally to multi-robot control problems, they have had a significant influence on that field of research. *Simmons et al.* [13.111] described a hybrid architecture designed for group-level coordination which employs

behaviors as a method for organizing low-level safety-critical controller code. Behaviors have also been used to structure controllers and networked communication in minimalist systems [13.112]. Some multi-robot research with a control-theoretic flavor has used separate executable processes that can be switched on and off dynamically depending on task constraints, in a manner very similar to behavior-based control [13.113].

Behavior-based controllers have also been built using genetic algorithms [13.114], in which the controller learned through coevolution five behavioral components (waypoint prediction, force field trajectory, speed regulation, reversing and heading alignment), enabling it to outperform all its opponents in a real time car racing game held during the 2007 IEEE Congress on Evolutionary Computation (CEC).

Behavior-based architectures have also been used in complex vision systems for identification rather than control. In those contexts, each behavior represents a small unit of visual computation, such as frame differencing, motion detection, and edge detection, resulting in biologically inspired vision and attention behavior [13.115, 116].

Behavior-based architectures have also been developed for the control and learning in humanoid robots. In the past, the Cog project demonstrated behavior-based control for articulated manual and eye-hand coordination [13.117, 118]. *Edsinger* [13.119] developed a lightweight behavior architecture for organizing perception and control of Domo. The architecture allows for specification of time-contingent behaviors and distributed computation, resulting in a real-time controller that allows Domo to operate in an environment with humans. *Kismet* [13.120] involved several behavior-based systems that controlled perception, motivation, attention, behavior, and movement in a human-robot interaction (HRI) context. Each behavior represented *Kismet's* individual drives and motivations. Situated modules and episode rules were introduced as part of an HRI architecture by *Ishiguro et al.* [13.121] and *Kanda et al.* [13.122]; they employed an ordered set of general-use situated modules and behaviors that are contingent on a condition, used in sequences defined by a set of task-specific episode rules.

13.6.1 Adaptive Behavior Selection – A Case Study

Designing robots capable of safely and effectively interacting with humans in real-world settings is one of the ultimate challenges in robotics. Representation and abstract reasoning are necessary to keep up with and adapt to the inherently complex properties of such environments and tasks.

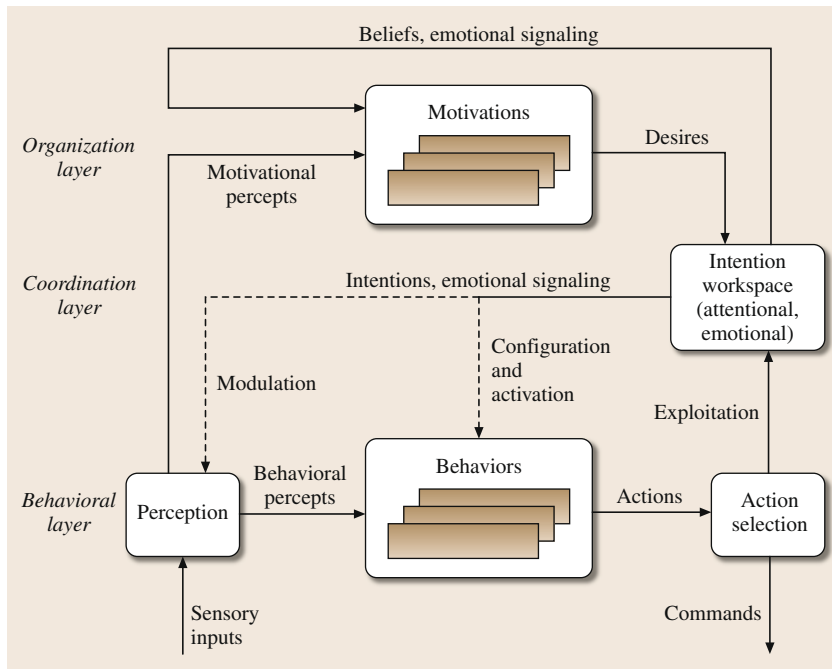

Fig. 13.4 Hybrid Behavior-Based Architecture (HBBA)

Adaptation in behavior-based systems [13.28] generally consists of modifying internal parameters of the behaviors, or modifying the set of activated behaviors. Many possible avenues to implement such mechanisms exist. One possibility consists of adding to a behavior-based architecture the idea of intentionally activating, monitoring, and configuring behaviors. An architectural framework based on this idea has evolved over the years, having been implemented on diverse robotic platforms and tested in various operational conditions:

- **EMIB** – Emotion, Motivation and Intentional Behaviors – has been applied to robots with different capabilities, such as a robot that uses activation variables, topological localization and mapping, and fuzzy behaviors to explore and characterize an environment [13.45, 46], and on an autonomous rolling robot that only uses simple sensors and a micro-controller to generate purposeful movements for conducting studies regarding on toddler–robot interaction [13.123, 124].
- **MBA** – Motivated Behavioral Architecture [13.125, 126]). In the American Association for Artificial Intelligence (AAAI) mobile robot competition and as shown in [VIDEO 417](#), **MBA** was used with the Spartacus robot to demonstrate how a behavior-based system could integrate planning and sequencing tasks under temporal constraints, interleaving planning and execution [13.127] (as in [13.128]

and [13.129]), and with spatial localization capabilities using a previously generated metric map. The system also used behavioral message reading [13.130], sound processing capabilities with an eight-microphone system for source localization, tracking, real-time sound separation [13.131, 132], and a touch screen interface to allow the robot to acquire information about where it is in the world, what it should do, and how it should do it [13.125].

HBBA – Hybrid Behavior-Based Architecture [13.133] – illustrated by Fig. 13.4, is the current instantiation of the architectural framework. The Behavioral Layer consists of behaviors that are activated and configured according to what are referred to as the Intentions of the system (derived by the Motivation Layer). Intentions are associated with the activation and configuration of behaviors and with the modulation of perceptual modules. The highest layer uses Motivations acting as distributed processes (just like Behaviors) and manifesting Desires for the satisfaction or inhibition of Intentions. The Intention Workspace processes these Desires to issue Intentions. The Intention Workspace can also provide Emotional Signaling (detecting situations based on models of how Behaviors are exploited over time [13.44, 134–136]), and generates Beliefs (i.e., knowledge about the interaction dynamics of the robot and the environment) which can be used to identify conflicts between Desires and their satisfaction. The objective

Fig. 13.5 Photographs of the front and back of the robot, IRL-1 (30 DOF and 55 sensors). DEAs stand for Differential Elastic Actuators (after [13.133])

is to have Intentions emerge from the interaction of independent motivations. Desires are communicated to the Intention Workspace, which plays a role similar to a coordination layer in a hybrid architecture, or to action selection with motivations acting as behaviors and Intentions emerging from the interaction of independent motivations. Our design requirements for the Intention Workspace module is to implement generic mechanisms (i. e., mechanisms that are independent of the robot's physical capabilities and intended usage) to generate Beliefs (i. e., data structures that represent desires, knowledge about the interaction dynamics of the robot and the environment), and identify conflicts between Desires and their satisfaction. The Exploitation link is used to derive information about the effective use of Behaviors as influenced by the events occurring in the world and the Action Selection mechanism. We believe that observing the exploitation of behaviors over time is an important source of information about the emerging functionality that comes from the Behaviors and the Motivations, because it combines both a representation of the environment (from the behavioral percepts associated with Behaviors) and of the control policy (from the internal decision-making processes).

HBBA is currently being used with IRL-1 [13.137, 138], an interactive omnidirectional platform shown in Fig. 13.5, [VIDEO 418](#) and [VIDEO 419](#).

IRL-1 has behaviors for safe navigation, recharge and social interaction (with gestures, voice and vision). Action selection is priority-based. Motivations are implemented to provide the intrinsic modes of operation of the robot (safe navigation while exploring the world, interact with people and ensuring energetic autonomy), to localize and plan paths to desired locations, and eventually to plan and schedule tasks [13.139]. Just like

action selection at the behavior-based level, the Intention Workspace plays a key role. More specifically, in HBBA, it involves:

- A tree representation of desires. Each desire can be associated with a particular configuration and activation of one or more behaviors. The tree representation of desires provides a general representation of Desires' interdependencies issued by the independent motivations, from high-level/abstract desires (e.g., *Deliver message*) to primitive/behavior-related desires (e.g., *Avoid obstacles*), allowing for behavior configurations to arise in a distributed fashion based on the capabilities available to the robot. This allows motivations to exchange information asynchronously on how to activate, configure, and monitor behaviors. For instance, one motivation may monitor the robot's energy level to issue a recharging desire, which would be associated with a *Recharge* behavior that would make the robot opportunistically detect and dock to a charging station. Meanwhile, if the robot knows where it is and can determine a path to a nearby charging station, a path planning motivation could add a sub-desire of navigating to this position, using a *Goto* behavior. If a person is detected, a social motivation may provide an alternative desire by engaging into a conversation to ask for guidance toward the nearest charging station. The robot would then have three alternative solutions to fulfill its desire to recharge.
- A representation of the history of behavior exploitations (similar to one described in Sect. 13.5.4), indexed by intentions. For instance, for the recharging desire example, if being guided by people reveals not to be as reliable as using the internal map, a preference could be given to the second option.

- An attention selection mechanism to module computational load, by percepts selection or output complexity reduction. For instance, artificial audition [13.131, 132] can be modulated to detect sounds, localize sound sources or separate sound sources depending on the presence of people surrounding the robot and its intentions to interact. A Simultaneous Localization and Mapping (SLAM) algorithm can change resolution depending on available processing load of onboard computers.
- An emotion-based mechanism to regulate conflicts between desires and intentions. Robot's adaptability in dynamic, continuous and unpredictable en-

vironments ultimately depends on the detection of the situations for which their regular decision-making process is not appropriate. Psychologists have identified that one of the functions of human emotion is to highlight these kinds of situations, allowing other cognitive processes to address them. Therefore, an emotional process that detect such situations from the use of temporal models of intentions could be beneficial [13.44]. This process does not rely on a priori knowledge of specific environmental conditions nor of the robot's mission objectives, but only on temporal analysis of how behaviors satisfy the robot's intentions.

13.7 Conclusions and Further Reading

This chapter has described behavior-based control, a methodology for single- and multi-robot control aimed at situated robots operating in unconstrained, challenging, and dynamic conditions in the real world. While inspired by the philosophy of reactive control, behavior-based systems are fundamentally more expressive and powerful, enabling representation, planning, and learning capabilities. Distributed behaviors are used as the underlying building blocks for these capabilities, allowing behavior-based systems to take advantage of dynamic interactions with the environment rather than rely solely on ex-

plicit reasoning and planning. As the complexity of robots continues to increase, behavior-based principles and their applications in robot architectures and deployed systems will evolve as well, demonstrating increasingly higher levels of situated intelligence and autonomy.

Interested readers can find more information regarding behavior-based systems in other chapters of this Handbook, as well as in *Brooks* [13.140], *Arkin* [13.22], in artificial intelligence and robotics textbooks [13.141, 142], and in introductory textbooks on mobile robot control [13.143–145].

14. AI Reasoning Methods for Robotics

Michael Beetz, Raja Chatila, Joachim Hertzberg, Federico Pecora

Artificial intelligence (AI) reasoning technology involving, e.g., inference, planning, and learning, has a track record with a healthy number of successful applications. So can it be used as a toolbox of methods for autonomous mobile robots? Not necessarily, as reasoning on a mobile robot about its dynamic, partially known environment may differ substantially from that in knowledge-based pure software systems, where most of the named successes have been registered. Moreover, recent knowledge about the robot's environment cannot be given a priori, but needs to be updated from sensor data, involving challenging problems of symbol grounding and knowledge base change.

This chapter sketches the main robotics-relevant topics of symbol-based AI reasoning. Basic methods of knowledge representation and inference are described in general, covering both logic- and probability-based approaches. The chapter first gives a motivation by example, to what extent symbolic reasoning has the potential of helping robots perform in the first place. Then (Sect. 14.2), we sketch the landscape of representation languages available for the endeavor. After that (Sect. 14.3), we present approaches and results for several types of practical, robotics-related reasoning tasks, with an emphasis on temporal and spatial reasoning. Plan-based robot control

Historical debates about the necessity and wisdom of employing symbolic reasoning in autonomous mobile robots notwithstanding (Chap. 13), there seems to be agreement now that some part or layer in the control system of such robots should or could include reasoning. Hybrid control architectures (Chap. 12) would be typical software structures for solving the difficult problem of amalgamating their contributions with those of other parts of the controller, yet guaranteeing suffi-

is described in some more detail in Sect. 14.4. Section 14.5 concludes.

ciently short control cycle times that the robot can act safely in a dynamic environment.

Symbolic reasoning is understood here in the classical sense of artificial intelligence (AI), i.e., deliberation based on symbols as in first-order predicate logic (FOPL) or Bayesian probability theory, but typically with restrictions and/or extensions thereof, which have to be traded off against each other to achieve a suitable combination of expressivity and inference speed.

14.1 Why Should a Robot Use AI-Type Reasoning?

If robots are to accomplish tasks that are too complicated for specifying the appropriate behavior for all possible situations beforehand, they should be able to reason themselves about what is the appropriate way to perform the task – even if the task is specified vaguely. In this setting, *reasoning* means inferring the needed knowledge from what is spelled out explicitly in the available knowledge. It further means *automated* reasoning using methods from AI including knowledge representation (KR) and inference, heuristic search, and machine learning.

To perform their course of action appropriately, robots need to reason about the actions they intend to perform, their intended effects, the unwanted side effects, whether they are executable in the respective situations, the goals the actions are to accomplish, and so on. Consider, for example, the seemingly simple task of picking up an object from a table. To do so, the robot has to decide where to go in order to pick up the object, which hand(s) to use, how to reach for the object, which type of grasp to apply, where to place the gripper, how much grasp force to apply, how much lift force, how to lift the object, where to hold it, and so on.

If programmers have to specify the decisions for every conceivable combination of object and task, the control program for picking up an object becomes very complex. But even this program would in most cases not suffice to generate competent robot behavior, because how the pickup action should be performed depends on the context, too – the state of the object, the task to be performed, the scene that the object is located in. If the object is a glass filled with juice, it has to be held upright and if it is a bottle the robot intends to fill a glass with, it should not grasp the top of the bottle. If the bottle is to be picked up in the middle of a cluttered scene, then grasping the top of the bottle might be the best choice. If the scene is cluttered and the purpose is filling a glass, then the robot might even have to re-grasp after picking up the object.

The situation gets even more complicated if the task is not a single action, but a compound activity such as

cleaning the table. In this case, AI reasoning methods can be employed to enable programmers to specify the course of activity very compactly: *for every object on the table put it where it belongs*. For such a vague plan to be a sufficient activity prescription, the robot has to infer the information needed to decide on the appropriate parameterizations of the pickup actions and it has to infer where objects belong depending on whether they are to be used again, are dirty, perishable, etc. Competently cleaning the table might also require the robot to think about the order in which it wants to put away the objects. It might decide to group the carry actions according to the place where the items have to be placed, or clean up perishable items first. It might reason about whether to stack items, get a tray and use that, and whether to leave doors of cupboards open.

Thus, an important task of AI reasoning techniques is: given a vague instruction, infer what is the appropriate action, what is the appropriate object to be acted on, what is the appropriate order of action executions, and what is the appropriate way of performing every action.

To deal with these issues, autonomous robots can represent and reason about aspects including the robots' capabilities, their environments, the objects they are to act on, their actions and the effects they cause, and other agents in the environment.

Important kinds of reasoning that robots should be capable of, therefore include the following:

- *Prediction* (often called *temporal projection*): inferring what will (probably) happen if the intended course of action is executed
- *Envisioning*: inferring (all) possible events and effects that will happen if a plan gets executed in a hypothetical situation
- *Diagnosis*: inferring what caused a particular event or effect in plan execution
- *Query answering*: given some knowledge preconditions for plan execution (e.g., a robot has to know the combination of a safe in order to open it), inferring pieces of knowledge that satisfy these knowledge preconditions.

14.2 Knowledge Representation and Processing

Reasoning requires that the reasoner – in our case, a robot – has an explicit representation of parts or aspects of its environment to reason about. Two questions come up immediately: what are suitable formats for such an explicit representation, and where does the represented knowledge come from?

The second question refers to the problem of generating and maintaining in real time a symbolic description of the robot's environment, or at least of some part of it, based on, possibly, a previous symbolic description and on recent environment information as by sensors and by communication with other agents. In full

generality, this problem is currently unsolved, involving **AI** fundamentals such as *symbol grounding* [14.1] and *object anchoring* [14.2]. So practical symbolic reasoning in a robot is restricted to that part of its knowledge that can be kept sufficiently recent. This includes, obviously, static knowledge about the environment, such as the topological elements and their relations in a building; transient knowledge available in symbolic forms, such as in facility management data bases; and, most challenging, symbolic data that has to be distilled from sensor data. Object recognition (Chap. 33) is a crucial ingredient to solve this; these issues will not be treated here.

This section deals with answers to the first question, i. e., formalisms suitable for representing knowledge. Suitability has two aspects here that are to be treated as two sides of one coin. One is *epistemological adequacy*: Does the formalism allow the targeted aspects of the environment to be expressed compactly and precisely? The other is *computational adequacy*: Does the formalism allow typical inferences to be drawn effectively and efficiently? There is a tradeoff between the two adequacies, given that very rich, expressive, and hence epistemologically appealing formalisms are typically accompanied by intractable or even undecidable inference problems, and vice versa. **KR**, then [14.3, p. xiii]:

is the field of AI that focuses on the design of formalisms that are both epistemologically and computationally adequate for expressing knowledge about a particular domain.

The plural in *formalisms* does not come by chance: there is no such thing as *the KR* language. The reason is twofold.

First, the archetype of **KR** languages, **FOPL**, is undecidable, i. e., any reasoner dealing with a language at least as expressive as **FOPL** is not guaranteed to terminate on a single query, let alone terminate fast. However, full **FOPL** expressivity is not always needed; for example, to represent a finite domain or to make restricted use of quantification may lead to decidable, and even tractable representation languages. Second, some

applications of **KR** and reasoning, like quite a number of applications in Robotics, require evidence rather than truth to be represented, and **FOPL**, in particular, does not come handy for doing that. So, there are good reasons, both for pragmatics and for epistemological adequacy, for having several representation languages – and that has happened in **AI**.

Table 14.1 lists in its rows four broad types of **KR** languages, which have been in use in Robotics. Description logics (**DLs**) are in fact a specific family of relational languages, of which there are decidable and tractable members. The table gives in its columns the *Assertions* of the language types, i. e., the language elements used to represent some domain; the *Queries*, i. e., the type of problems that a reasoner in a particular language is supposed to solve; the *Subject* that a particular language of the respective type is normally used for representing; and *Examples* of such languages. The remainder of this section sketches generic **KR** in logic and in a probabilistic language, including the respective types of inferences. Specific robotics-related instances of reasoning on the symbol level are described in the following section, in particular, reasoning about temporal and spatial objects and relations, which are pervasive in a robot's reasoning.

14.2.1 Logic-Based Reasoning

As stated above, **FOPL** does not qualify for a **KR** formalism in the above-mentioned sense of being both epistemologically and computationally adequate for typical application domains – in many cases, it is neither of the two. Yet, it is the background for understanding conceptually and mathematically general relational languages.

In this short text, we can only introduce **KR** in logic by way of example, assuming familiarity with the basic notions of **FOPL**. For more comprehensive and formal treatments, we refer to the broad body of literature: every typical **AI** textbook introduces **FOPL**, and [14.4, 5] are no exceptions; [14.6] is a principled introduction to logics; [14.7] a practical one, and [14.8] a concise mathematical one.

Table 14.1 Abstract categorization of main relational languages as used in Robotics (see text for explanations)

	Assertions	Queries	Subject	Example
General relational languages	Sentences, theories	(Logical) consequence	Situations, contexts, relations	FOPL , prolog, situation calculus
Description logics	A-Box and T-Box contents	Subsumption, consistency	Ontologies, encyclopedias	OWL-DL
Probabilistic languages	Prior and conditional probabilities	Conditional probabilities	Evidence	Bayesian networks
Languages for temporal and spatial reasoning	Temporally and/or spatially qualified sentences	Logical consequence, satisfiability, minimal representation	Desired or observed spatial/temporal state of affairs	LTL , IA , TCSP , RCC , ARA ⁺

Representing knowledge in some variant of logic facilitates to draw inferences from that knowledge using provably sound and/or complete calculi. Automated deduction is a subfield of logic and AI that offers a healthy number of very powerful implemented deduction systems that can readily be used. Reference [14.4, Chap. 9] gives an introduction; [14.9] is a traditional handbook covering all the classical topics of logical reasoning.

Relying on logical inference, a robot could deduce a large number of facts that might otherwise be hard or impossible to get at. For example, assume a robot perceives by acquiring and interpreting sensor data, that the door D_{509} in an office building is currently closed: $Closed(D_{509})$ expressed in some ad hoc FOPL language, assuming intuitive interpretations of symbols. Let us further assume that the robot's base of static knowledge about the building contains the sentences

$$\begin{aligned}
 &Connects(D_{509}, C_5, R_{509}) , \\
 &Connects(D_{508}, C_5, R_{508}) , \\
 &Connects(D_{508a}, R_{508}, R_{509}) , \\
 &\forall d, l_1, l_2. [Connects(d, l_1, l_2) \leftrightarrow \\
 &\quad Connects(d, l_2, l_1)] , \\
 &\forall d. [Closed(d) \leftrightarrow \neg Open(d)] , \\
 &\forall l. [At(l) \rightarrow Accessible(l)] , \\
 &\forall l_1, l_2. [Accessible(l_1) \rightarrow \\
 &\quad (\exists d. [Connects(d, l_1, l_2) \wedge Open(d)] \rightarrow \\
 &\quad Accessible(l_2))] .
 \end{aligned} \tag{14.1}$$

Constants D_i and variable d denote doors; R_i denote rooms; C_i corridors; variables l, l_i denote locations, i. e., rooms and corridors. Assume that the robot's localization tells it its current room or corridor location as $At(\cdot)$.

Then, assuming the robot knows it is $At(C_5)$, observing $Closed(D_{509})$ entails $\neg Open(D_{509})$, and, more interestingly, that $Accessible(R_{509})$ is true only if $Open(D_{508}) \wedge Open(D_{508a})$ is true. So, performing, for example, a delivery task to room R_{509} , the robot may replan its route through R_{508} , unless at least one of D_{508}, D_{508a} is known to be closed. If the status of one or both of them is unknown (neither $Open(\cdot)$ nor $Closed(\cdot)$) is entailed by the current knowledge base), then accessibility of R_{509} can be neither proven nor disproven. That would leave open the option of planning the route through D_{508} and D_{508a} , gathering their required statuses on site.

So, as this little example may show, FOPL is a powerful representation and reasoning tool. Moreover, its theory is very well understood. In particular, it is well-known that consequence in FOPL is in general undecidable, that means, a sound and complete deduction

algorithm cannot even guarantee termination for some particular inference attempt, let alone speedy results.

However, that does not mean logic as a representation and inference tool needs to be completely disposed of. Many applications do not require the full expressivity of FOPL. Moreover, there are many interesting language subsets of FOPL that are decidable and can be handled by algorithms that are efficient in most practical cases. So considerable effort by the KR community has gone into identifying FOPL subsets and fitting inference procedures that qualify for being both epistemologically and computationally adequate for a broad number of applications. We will consider two of them in more detail: propositional logic and description logics; we will then go briefly into using logics for high-level robot control.

Propositional Theories

In quite a number of practical cases, FOPL theories (sets of formulas) represent in fact finite domains. Logically speaking, they have finite Herbrand universes or can at least be recast in a form such that they have. In this case, it may still be handy to express the domain theory in FOPL syntax, but all that goes beyond a purely propositional theory is just for notational convenience. For example, an axiom stating that a robot can only be in one location (room or corridor) at a time

$$\forall l_1, l_2. [At(l_1) \rightarrow (\neg At(l_2) \vee l_1 = l_2)] \tag{14.2}$$

can be *flattened* for a finite building into the, clumsy but equivalent, form handling all locations explicitly, for example in a six-storey building

$$\begin{aligned}
 At(R_{001}) &\rightarrow [\neg At(R_{002}) \wedge \dots \wedge \neg At(R_{514}) \wedge \\
 &\quad \neg At(C_0) \wedge \dots \wedge \neg At(C_5)] , \\
 At(R_{002}) &\rightarrow [\neg At(R_{001}) \wedge \dots \wedge \neg At(R_{514}) \wedge \\
 &\quad \neg At(C_0) \wedge \dots \wedge \neg At(C_5)] , \\
 &\dots
 \end{aligned} \tag{14.3}$$

where every ground (variable-free) instance of a predicate, such as the At instances above, are to be considered as propositional variables, regarding textual identity.

The good news here is that the corresponding *flat* theory to a FOPL theory over a finite Herbrand universe is propositional, hence, it is decidable. Moreover, under some practical conditions – e.g., if the variables in the FOPL theory are sorted (that is, the information is available that the variables l_1, l_2 , e.g., range over rooms and corridors) – it can even be generated mechanically from a more compact FOPL syntax.

The potentially bad news is that the now propositional theory may of course consist of a huge amount

of propositional sentences: in general, as all combinations of variable substitutions in all FOPL sentences need to be generated, the growth is multiexponential in terms of the domain sizes of the FOPL variables.

However, the technology for propositional satisfiability checking or *model checking* is making considerable progress, allowing propositional theories with thousands or even tens of thousands of variables to be handled in the order of seconds of computation time on regular hardware. The respective methods are particularly efficient if many models exist for a satisfiable propositional formula or if the truth or falsity of many ground facts is known a priori (such as $At(C_5)$ for a robot by independent localization). Both is often the case in practical KR.

References [14.4, Chap. 7.6] and [14.9, Chap. 24] give introductions to model checking. One modern family of methods is based on the classical Davis–Putnam (DPLL) algorithm [14.10]. It attempts to construct systematically a propositional model of a given theory, efficiently propagating interpretation constraints for variables. Another family of algorithms applies local search techniques, attempting to generate interpretations using random (Monte Carlo) variable assignments. Reference [14.11] is a Web page maintained for the annual satisfiability checking competitions held together with the annual SAT (*Theory and Applications of Satisfiability Testing*) conferences; it gives a continuously updated overview over current top-performing satisfiability checking systems.

Description Logics

DL have emerged as rigorous formalizations of somewhat intuitive KR forms of the AI of the 1970s, namely, semantic networks and frame systems. Logically speaking, DLs, of which there is a considerable variety, form a certain family of subsets of FOPL, some of which are decidable or even tractable.

There are two parts of representing knowledge about a particular domain using a DL language. First, the *upper ontology* of the domain is formulated. It introduces the general domain concepts as well as relations between these concepts. A particularly interesting type of relations occurring in all ontologies is the superclass-subclass relation. Given that most DLs – as part of the means for enforcing decidability – strictly disallow cyclic relations between concepts to be specified, the superclass relation imposes a hierarchical taxonomy on concepts, which serves for defining property inheritance, much like in object-oriented programming. This first part of a DL-based domain representation is, for historical reasons, often called the *T-Box* (or *terminological knowledge*).

A *concept* in the DL language corresponds to a unary predicate. To give an example, an ontology of robot navigation domains might include concepts like *Door*, *Location*, and so on. The concept hierarchy is built by defining concept equality = or a subconcept property, e.g., $Room \sqsubseteq Location$, and $Corridor \sqsubseteq Location$. Concepts can be combined using concept conjunction, disjunction, and negation (\sqcap, \sqcup, \neg , respectively), allowing, e.g., concept definitions like $Location = Room \sqcup Corridor$, $Door = Closed \sqcup Open$, and $Open = \neg Closed$.

Roles in a DL language correspond to binary predicates, such as *leadsTo* for a door and a location. Inversity, intersection, and union of roles are defined as expected, where $leadsTo = leadsFrom^{-1}$ is an example for defining inverse roles. Roles can be composed, such as in defining $adjacent = leadsFrom \circ leadsTo$ (location l is adjacent to m if and only if some door connects them). Finally, concepts and roles can be combined for defining new concepts and roles. In particular, it is possible to quantify over *role-fillers*, i.e., the individual objects (see next) that can be consistently substituted for role arguments. For example, one could define $BlockedLoc = Location \sqcap \neg \exists leadsFrom.Open$ (assuming the intuitive binding rules of the operators). Different variants of DLs differ in what operators they make available; the set of available operators and additional constraints on definitions shape both the expressivity and the computability of the respective DL variant – the spectrum ranges from undecidable to tractable. See [14.3] for details.

As the second part of domain representation using DLs, individual objects have to be introduced into the language of concepts and roles. This part of the domain representation is called *A-Box* (or *assertional knowledge*). For example, $Room(R_{509})$, $leadsTo(D_{509}, R_{509})$, and $Closed(D_{509})$ could be asserted.

DLs have a number of reasoning services to offer, which are based on logical inference in a given T-Box and A-Box. They include consistency of the concept definition, subsumption and disjointness of concepts, consistency of the A-Box wrt. the T-Box, concept and role instances, all of which are decidable in many DLs. Given the T-Box and A-Box rudiments above, it would, e.g., be concluded that everything is consistent and that $BlockedLoc(R_{509})$ (note that only door D_{509} is known here to lead to R_{509} !). These DL inferences are theoretically intractable, but run efficiently in most of practical cases.

Reference [14.3] provides a comprehensive overview of DL. In 2004, the WWW consortium (W3C) has defined the Web Ontology Language OWL [14.12] as a technical basis for the Semantic Web, which was followed by OWL 2 in 2009 [14.13].

Part of the language is **OWL-DL**, a classical **DL** in the sense just described. **OWL-DL** ontologies are publicly available over the Web. Reference [14.14] gives a tutorial introduction.

Logics for High-Level Robot Control

Robot domains are dynamic by nature, including at least one physical agent, namely, the robot. Capturing that in logic-based formalisms is possible and has been undertaken, as introduced in [14.4, Chap. 12.3]. However, it poses some conceptual and technical problems, which we will describe at the end of this section on Logics.

Very briefly, one of them comes from the requirement of expressing concisely and reasoning efficiently with logical models of events in general, and actions in particular. Logically speaking, an individual action changes the truth value of a limited number of facts, leaving everything else as it was. For example, modeling on some abstract level the action of going from one location to another as atomic, it changes the robot's current location before and after; depending on the modeling, it may also change the battery state and the mileage count; but it does not change the layout of the building or the name of the president. The problem of formalizing actions concisely in a logical language so that they allow facts to be inferred efficiently that may or may not have changed after applying a sequence of actions, has been termed the *frame problem*. It has received much attention in the literature; there are now a number of practical solutions to it.

Another problem concerns knowledge-base update made necessary by independently changing facts. Consider, for example, a robot sitting – as it is told by its self-localization – in front of some door *D*, which is believed to be open, but the robot perceives a closed door. Logically, this is a contradiction. Now there are in theory several ways to make the knowledge and the perception consistent. One is to assume that *D* has been closed since learning that it was open – probably the most intuitive explanation. Logically just as good would be, e.g., that the perception is faulty, or that the robot has been teleported in front of a known closed door. Among these *explanations*, some are more intuitively plausible than others; logically, some would require less formulas of the knowledge base to be withdrawn and should therefore be preferred. Ideally, after replacing an old piece of information with a new one, one would have to make sure that the consequences of a retracted formula are no longer believed.

Theoretically, these problems are arbitrarily difficult. Practically, they can be sufficiently restricted to allow solutions within a neat logical framework. Typical solutions would introduce some notion of state or holding period for formulas, following the clas-

sical example of the situation calculus [14.15]. That allows change to be tracked. Typical solutions would also give up completeness of inference, resorting to a Prolog-like inference engine. Three examples for such solutions with reported applications in robot control are GOLOG [14.16], event calculus [14.17] and FLUX [14.18]. Another family of solutions would model the course of time in a more fine-grained way than switching between states. Temporal logics are appropriate here, and the temporal action logic (**TAL**) is an example, which has even been integrated in a performer planner [14.19]. It leads to a more sophisticated form of temporal reasoning that will be treated in Sect. 14.3.

14.2.2 Probabilistic Reasoning

KR formalisms based on logics are worth considering whenever factual knowledge is to be represented, from which consequences are to be queried. However, part of the knowledge that a robot might use about its environment does not really have this character.

Uncertainty is one of these traits, or rather, a whole family of them, as uncertainty is in itself an overloaded concept. *Lack of knowledge* is one of its aspects. Logics can handle this insofar as truth or falsity of some facts may remain undetermined. If too much is undetermined in a knowledge base, logics will no longer be able to make interesting deductions though, as *everything is possible* logically. Yet, the different possibilities may differ considerably in likelihood, according to intuition. The point here is to represent and reason about *evidence*.

The field of **KR** has adopted Bayesian probability as a means for representing and reasoning with evidence, using correlations between facts rather than strict implications. Note that this approach amalgamates different sources of lack of precision and completeness of knowledge. Some piece of knowledge may be unknown because it is in principle unknowable, or because it was judged too costly to build a precise theory or determine all information relevant for making a sound deduction. In either case, working with probabilities rather than binary truth values can serve as an approximation. Note that the notion of truth is still the same here as in classical logics: *objectively*, a fact is supposed to be either true or false; probability just models the *subjective* evidence that the fact is true.

We next describe two popular and powerful representation and processing formats for probabilistic knowledge: Bayesian networks (**BNs**) and Markov decision processes (**MDPs**). In analogy to Sect. 14.2.1, we here assume familiarity with the basic notions of probability theory. Reference [14.4, Chap. 13] gives an

excellent basic introduction; for a more comprehensive treatment, there is a large variety of introductory textbooks around, [14.20] being an example.

Bayesian Networks

Inference in Bayesian probability theory basically means to infer the probability of some event of interest, given prior and dependent other relevant probabilities. Practically, an important type of probabilistic inference is *diagnostic reasoning* from observed effects back to hidden causes, given rules that specify conditional probabilities from causes to effects. So the problem is, for a potential cause C and an observed effect E : Given prior probabilities $P(C)$ and $P(E)$ and the conditional probability $P(E|C)$, determine the posterior $P(C|E)$. The solution is of course given by the Bayes rule as

$$P(C|E) = \frac{P(E|C)P(C)}{P(E)}. \quad (14.4)$$

However, like in logical reasoning, the theoretically appealing principle turns out to be impractical if applied naively. Consider that not just one effect E may be observed, but E_1, \dots, E_n ; moreover, not all of them are conditionally independent. A generalized form of the Bayes rule to calculate the correct posterior is straightforward, but who can specify all the conditional probabilities involved – in the worst case $O(2^n)$ of them, where n may easily range in the hundreds in practical cases?

Until the late 1980s, this problem was more or less circumvented. One way to do so was to treat the E_i in bad faith as independent: simply take the n individual conditional probabilities $P(E_i|C)$ and use them for approximating straightforward the full joint probability distributions. Reference [14.4, Chap. 14] reviews this and other alternative approaches.

The solution used ever since it has appeared [14.21] is *Bayesian networks* (BN), more recently subsumed under the more general concept of *graphical models*. The idea is to represent the random variables as nodes in a directed acyclic graph, where a node is directly preceded by a set of parent nodes if and only if it is directly conditionally dependent on the corresponding parent variables. So the huge full joint probability distribution is broken down into many, typically very small, *local joint probability distributions* without loss of information, the trick being to use the typically many known conditional independences among variables to reduce the representational and inferential effort drastically.

Figure 14.1 shows a simple BN expressing that D is dependent on B and C , with probabilities given by a conditional probability table which specifies locally the joint probability distribution. In addition, the struc-

Fig. 14.1 Structure of a simple Bayesian network. It is associated with conditional probability tables. (The one for D , dependent on B and on C , is omitted)

Fig. 14.2 Unfolding of a simple DBN over two time slices representing two successive states. Variables x denote states, u denote actions, and z denote measurements. The structure of each individual slice (signaled by identical variable subscripts) is invariant over time

ture says that D is independent from A , given B and C (a node is independent from its ancestors, given its parents), and that B is independent from C , given A , i.e., $P(C|A, B) = P(C|A)$ and $P(B|A, C) = P(B|A)$.

Network inference can be interpreted in both directions. Bottom up, a BN enables to explain an observed phenomenon using the known conditional probabilities (diagnosis). For example, if D is observed, the likelihoods of its known causes (B or C) can be inferred. Top down, a BN enables to propagate evidence to compute the probability of a phenomenon, e.g., to compute the probability of D given A (causation).

For systems evolving over time, for which the Markov property holds, i.e., a state of a system variable in some state depends on no variables earlier than the previous state, a BN representation takes on a particular form, a *dynamic Bayesian network*, DBN. Assuming that the dependences among variables within a state remain constant over time, and assuming further that a variable x at different states is represented as a family of variables x_1, \dots, x_t, \dots , a DBN unfolded into a BN has a particular structure, as sketched by example in Fig. 14.2. The variables representing a new state correspond to a new BN slice, which reproduces the structure of the previous state representation and whose nodes depend only on each other and on nodes represent-

ing the previous state. This locality allows inference in DBNs to be efficient.

Markov Decision Processes

In the context of robot control, uncertainty is induced by perception, action, and incompleteness of prior knowledge about the environment, all of which are related. Perception uncertainty results from sensor noise, from occlusion, from interpretation ambiguities, and other effects. Action uncertainty results from approximate action models (e.g., wheel slippage), unsuccessful action (e.g., grasping failure), or other practically unavoidable effects.

Figure 14.3 depicts this uncertainty laden interaction between the robot and its environment.

Probabilistic representations are used to cope with these uncertainties. Planning being a sequential decision problem, MDP and, in the case of partial observability of the environment, partially observable Markov decision processes (POMDPs) [14.22] are widely used to address them. The Markov assumption, which is the hallmark of this approach, is that a state s_n of the system depends only on the previous state s_{n-1} and the action that lead to s_n , and not on any earlier states.

Under this assumption, an MDP is formally defined by four components $\langle S, A, T, R \rangle$ where S is a finite set of states, A is a finite set of actions, $T : S \times A \rightarrow S$ the transition function defining the probability of state change

upon application of a given action at time t

$$T(s, a, s') = P(s_{t+1} = s' \mid s_t = s, a_t = a) . \quad (14.5)$$

T is known and provided as a table of transition probabilities. Finally, $R(s, a)$, $R : S \times A \rightarrow \mathbb{R}$, is defined as the *reward* received by the system after achieving action a leading to state s . Often, the reward is associated with the state only ($R(s)$). In the sequential process, the rewards are supposed to be additive. Solving an MDP is an optimization problem in which the sum of the expected rewards, called the *utility*, is maximized. MDPs suppose that the rewards are already known. When this is not the case, the robot can acquire them through experience. One technique to do so is reinforcement learning, as described in Chap. 15. Figure 14.4 shows an example of a simple MDP.

There are two main methods to solve an MDP. In the *value iteration* (VI) method, the first step is to compute the utilities $U(s)$ for all states, and the second step is to compute the optimal *policy* $\pi^*(s)$ which provides, for each state, the optimal action. Computing the utilities iteratively is based on the Bellman equation [14.23]

$$U_{i+1}(s) = R(s) + \gamma \max_a \sum_{s'} T(s, a, s') U_i(s') , \quad (14.6)$$

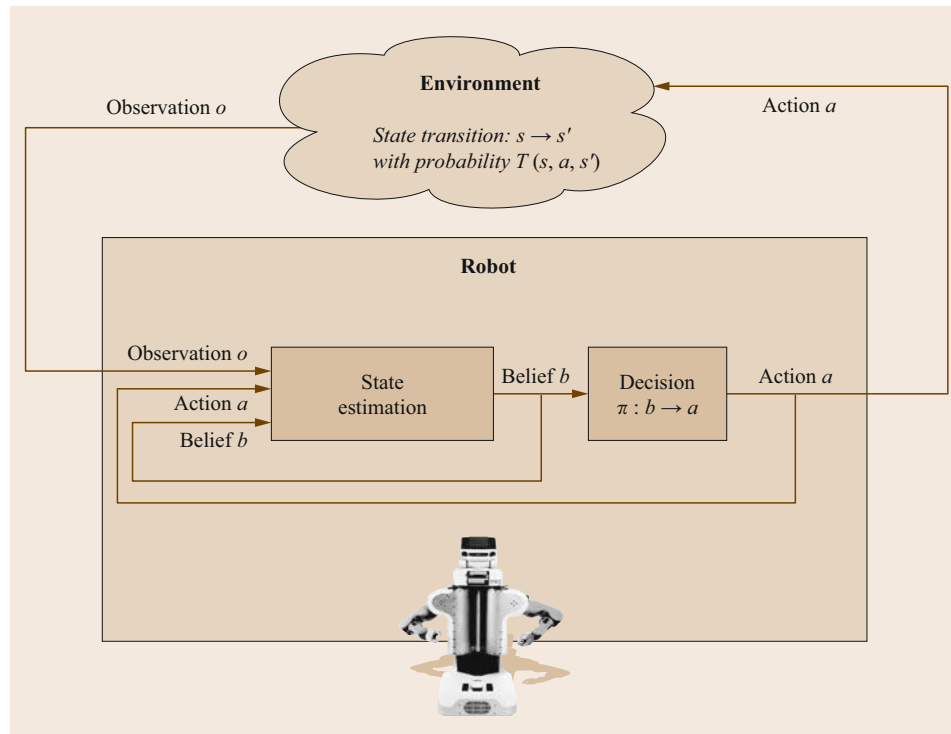

Fig. 14.3 The robot acts on its environment producing a new state with a given probability. Knowledge of the robot about state results from its observation and is also uncertain. Its decisions are taken based on its beliefs

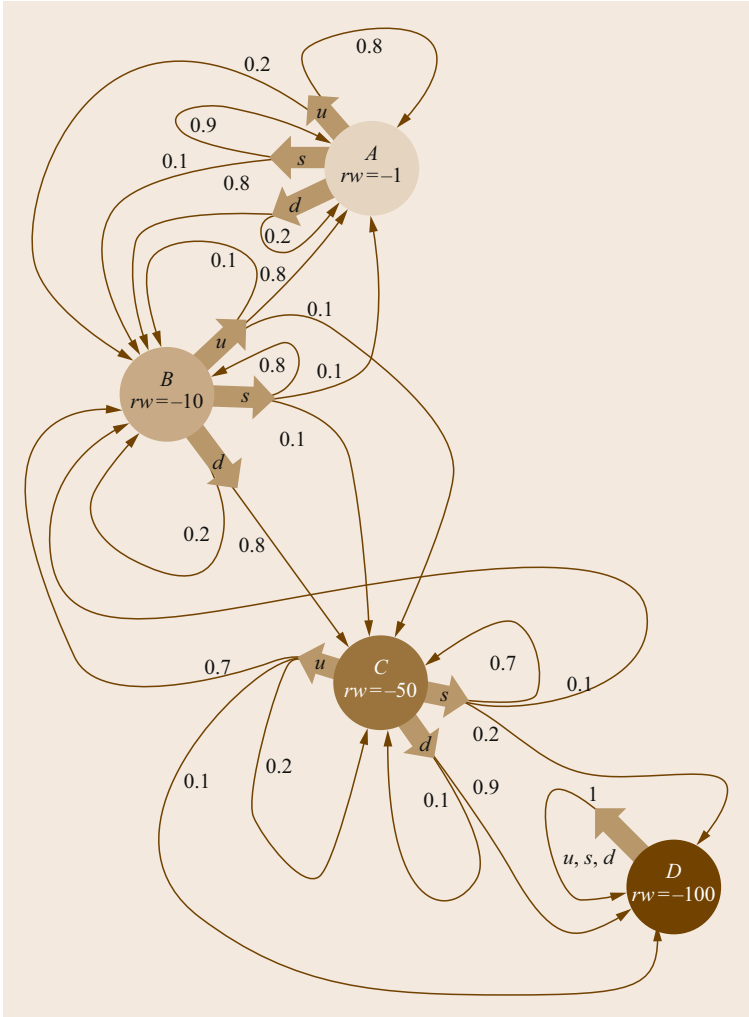

Fig. 14.4 A representation of an **MDP**. In this example, states *A*, *B*, *C*, *D* have associated rewards (-1 , -10 , -50 , -100). There are three possible actions in each state, *u*, *s*, *d*, each have a given probability (shown on the arrows) to lead to another state

where $0 < \gamma < 1$ is a discount factor. After computing the utilities, the optimal policy is the one that provides the best action (i.e., the one maximizing the utility) for each state. This is computed by $\pi^*(s) = \arg \max_a \sum_{s'} T(s, a, s') U(s')$. So the result of the **MDP** is the best local decision. A policy is an a priori computation of the best sequence of actions, which is guided by the maximization of a global reward instead of just reaching a goal with minimal cost, as in classical planning. So a policy is not a plan of actions that has to be strictly executed. Since it already takes uncertainties in action execution into account, the policy can be pursued whatever the outcome of action execution.

The second method is called *policy iteration (PI)*. Here one starts with an initial (e.g., random) policy π and, through an iterative algorithm, tries to improve it gradually by looking for the actions that augment utility.

In conclusion, in a deterministic setting, the solution to a planning problem is a sequence of actions. In an observable stochastic setting, the solution is a policy defined by the best local decision.

Partially Observable Markov Decision Processes

In the (realistic) case where the robot has no full access to the environment, decision making must be made under partial observability. To that end, the **MDP** formalism is enriched with an observation function that provides uncertain knowledge. A **POMDP** is defined by six components $\langle S, A, T, R, \Omega, O \rangle$. The first four describe an **MDP**. Ω is a finite set of observations o . $O : S \times A \rightarrow \Omega$ is the observation model $O(s', a, o)$ (derived for the robot sensor models) that provides the probability to obtain observation o after action a which has lead to state s' . The robot *belief state* is the probabil-

ity distribution over all states, i. e., all the probabilities of being in all the states. The belief to be in a given state is usually noted by $b(s)$. The belief is updated after an action and observation by

$$b'(s') = \alpha O(s', a, o) \sum_s T(s, a, s') b(s), \quad (14.7)$$

where α is a normalization constant.

Although partial observability is a typical case for robots acting in mundane environments, and hence POMDPs are the more adequate formalism for mod-

eling action and observation, POMDP-based models are often avoided. The reason is that calculating optimal POMDP policies is impracticably complex. Mostly, solving a POMDP is based on approximate or derived methods, such as working with the corresponding belief MDP of a POMDP, which results from considering the (fully observable) belief function induced by the POMDP.

A good example of using Markov processes for modelling and solving robotics decision-making problems, combining task planning, and motion planning is provided in [14.24].

14.3 Reasoning and Decision Making

The main motivation for developing reasoning capacities in robotics is to enable robots to make decisions about their future actions. This is why planning was one of the main early research topics in AI, within the SHAKEY project (📺 VIDEO 704), resulting in the seminal STRIPS planner [14.25]. Designing a planning system requires to address three main questions:

- How to represent the world?
- How to represent actions?
- How to guide the plan search process?

According to the formalism used to answer these questions, the planning system will cope differently with the constraints of the real world, and this is an essential issue in robotics. As mentioned above, early planning techniques were based on first-order predicate logic (FOPL) for representing knowledge, and the limitation of FOPL when facing the uncertainties of the real world has lead to adopt probabilistic representations and probabilistic reasoning to cope with real situations.

World Representations. Classically, when reasoning at the symbolic level, knowledge about the world is represented as *states* which are sets of logical propositions such as *Ontable(Cup)*. Under the closed world assumption, the facts that have the value FALSE are not represented in the states of the world. In order to deal with uncertainties, instead of having TRUE/FALSE values, the propositions have a probability distribution of being true.

Representation of Actions. In classical planning, as introduced by STRIPS, actions modify the state of the world and are defined by three sets of predicate lists. The predicates that should be true for the action to be feasible are the preconditions. The set of predicates that become TRUE after the action is executed is the ADD list. The set of predicates that becomes FALSE after action execution is the DELETE list. The plan-

ner includes a unification procedure to determine which predicates correspond to the propositions describing the world states. Taking into account uncertainties in action execution leads to including a probabilistic characterization of their outcome.

Search. Finding the most adequate action is based on a search algorithm in the state space. The state space is an implicit graph given by the initial state and a successor function that provides the states immediately adjacent to a given state. Each action, which represents the transition from one state to its successor, has a given cost. The well known A* algorithm [14.26] was proposed in 1968, again within the SHAKEY project, to address the search problem. The planning algorithm, based on this search, recursively selects the action that would produce the current goal state (or a subgoal thereof), and under certain conditions the optimal (i. e., least cost) solution is found.

This classical planning scheme is not able to cope with uncertainties because it is based on FOPL representations. The only way it can do that is through plan mending or replanning (Sect. 14.4). When probabilistic representations are used, the plan search will adopt a very different scheme as explained in Sect. 14.2.2.

However, reasoning in AI and robotics involves much more than sequential planning. Robots act in the real world in which action duration determines success or failure. They have to consider events occurring at given instants and situations that unfold over time. Temporal relations and an appropriate temporal logic are necessary to represent and reason about time. Section 14.3.2 discusses temporal reasoning.

Another central issue is reasoning about space. What does it mean exactly when we represent a piece of knowledge by the predicate *Ontable(Cup)*, or *Near(Robot, Table)*? How to express spatial relationships symbolically from sensor data? This involves

specific formalisms as well which are developed in Sect. 14.3.3.

14.3.1 Using Multiple Knowledge Representation Formalisms

Automated planning carries an immediate appeal for robotic applications: the actions a robot should perform to achieve a goal are obtained as a result of reasoning in a model which can be changed to suit different environments, physical capabilities, and tasks. Yet reasoning about action per se is not a silver bullet for robot programming. As noted earlier, obtaining competent robot behavior by reasoning in a model crucially depends on the epistemological adequacy of the modeling language. As a case in point, let us elaborate on our initial example: imagine a waiter robot with two arms that has to serve meals to guests in a restaurant. The robot would have to reason about time in order to infer that cold beverages should be delivered before they get warm. Food needs to be served in front of guests, hence the robot should be capable of some form of spatial reasoning. It should be capable of reasoning about resources, e.g., infer that it cannot hold more than two parts of the meal simultaneously with its two arms, or that its tray can only accommodate a limited number of dishes. A DL ontology might inform the robot that all mugs in the cupboard are clean – hence, committing to a particular mug at planning time is not necessary – or that a cup or a mug both work well for serving coffee. Most of this knowledge is difficult or impossible to model in *classical* planning models [14.27], which are limited to describing the causal relations that exist between actions and predicates in FOPL.

The types of knowledge a robot should possess ultimately depend on the application. It should be however evident that – short of encoding this knowledge in FOPL, which is computationally inadequate – several models expressed in different formalisms are necessary in most meaningful domains. Note also that any plan containing actions that are to be executed by a robot should also be translated to actionable metric terms that are understandable by the robot. For instance, specific positions in which objects are to be placed, locations to navigate to, and action dispatch times should be indicated in the plan. Finally, the knowledge represented in different models a robot should use for reasoning (the causal model being only one of these) often presents nontrivial interdependences: the capacity of the robot's tray (resource model) determines the number of trips a robot has to perform to and from the table it is clearing (causal reasoning), the type of meal (ontological model) may affect the spatial layout of the cutlery (spatial reasoning), and the time it takes for a beverage

to get cold (temporal model) will affect the order of goal achievement (causal reasoning). The development of problem solving algorithms that account for these interdependences is an active topic of research. An overview of recent results in this direction is provided in Sect. 14.3.4.

Of particular interest to this discussion are temporal and spatial KR formalisms. Several temporal and spatial logics possess properties that make them both epistemological and computationally adequate for a variety of robotic problems. Below, we outline the principal temporal and spatial KR formalisms that are relevant to robotics.

14.3.2 Reasoning About Time

Linear temporal logic (LTL) [14.28] is a decidable propositional logic which provides a means to describe how execution paths will evolve in the future. The temporal operators \bigcirc (next), \Box (always), \Diamond (eventually), \mathcal{U} (until) and \mathcal{R} (release) are used to represent conditions on the state of a system. For instance, *the robot will eventually place the cup on the table* (reachability), *the robot will never serve a cold coffee* (safety), and *the robot will always reach its charging station before its battery is discharged* (liveness). A fragment of LTL (specifically, syntactically co-safe LTL formulae [14.29]) has become relevant in robotics because of its ability to predicate upon discrete temporal properties of motions. For example, an exploration robot may be required to visit locations *A*, *B* and *C* in a predetermined sequential order; or conditions like *avoid C unless A or B have been visited, and always avoid D*. Given such temporal goal specifications, it is possible to compute motions that satisfy these goals with probabilistic roadmaps (PRMs) [14.30, 31].

LTL formulae express qualitative temporal specifications, thus offering the domain expert a means to specify conditions on execution at a high level of abstraction. LTL does not however consider that robot actions have a temporal extent, and that the temporal extents of different actions may be required to have specific relations. The qualitative temporal logics point algebra (PA) [14.32] and interval algebra (IA) [14.33] can be used to capture (and enforce) such relations. Specifically, they allow to represent qualitative temporal relations among temporal variables. Variables in PA represent time points, which can be used to represent events, such as *the robot has reached the table*, or start/end times of actions, such as *the robot starts to place a mug on the table*. In IA, variables represent time intervals, e.g., *the robot navigates to the table*, or *the robot places the mug on the table*. The basic PA relations are the three temporal relations $\{<, >, =\}$. All

unions of these relations (\leq , \geq , \neq , the universal relation \top , and the empty relation \emptyset) are also valid **PA** constraints. In **IA**, constraints represent temporal relations among temporal intervals. The basic **IA** relations B_{IA} are the 13 possible temporal relations between intervals, namely *precedes* (p), *meets* (m), *overlaps* (o), *during* (d), *starts* (s), *finishes* (f), their inverses (e.g., p^{-1}), and *equals* (\equiv) (Fig. 14.5). A constraint in **IA** is a disjunction of basic relations $\{r_1, \dots, r_n\} \in B_{IA} \times \dots \times B_{IA}$. Going back to our example, a relevant piece of temporal knowledge for our waiter robot is that the action of picking the mug temporally overlaps the fact that it is holding the mug, i. e., the **IA** relation

$$\text{Pick(Mug)} \{o\} \text{Holding(Mug)} . \quad (14.8)$$

This knowledge in fact represents the qualitative state of affairs in the presence of a successful pick-up action, whereas the contingency in which the mug slips from the robot's gripper (an all too common occurrence with today's robots!) can be expressed by the temporal relation

$$\text{Pick(Mug)} \{d^{-1}\} \text{Holding(Mug)} . \quad (14.9)$$

A set of variables and constraints in **PA** or **IA** constitutes a constraint satisfaction problem (**CSP**) [14.34]. A fundamental reasoning problem in temporal **CSP**s is to test the *satisfiability* of the **CSP** – assessing whether a substitution of temporal values to variables exists that satisfies all constraints. A related problem is that of computing the *minimal* representation of a given **CSP**, that is, the equivalent **CSP** formed by the strongest implied constraints. Both problems are tractable for **PA** and for several fragments of **IA** [14.35]. A particularly useful example of tractable subalgebra of **IA** is the set of *convex* **IA** relations [14.36]. For example, $\{b, m, o\}$ is a convex **IA** relation, whereas $\{b, o\}$ is not. These good

computational properties can be leveraged by robots during plan execution. Ensuring robust execution in the case of our waiter robot picking a mug need not be hard-coded as an ad-hoc status checking procedure into the implementation of the pick up action. Conversely, it can be modeled as a simple relation as above, and its verification can be cast as a **CSP** containing the relations

$$\begin{aligned} &\text{Pick(Mug)} \{o\} \text{Holding(Mug)} , \\ &\text{Pick(Mug)} \{d^{-1}\} \text{Holding(Mug)} . \end{aligned} \quad (14.10)$$

The first constraint represents the requirement we expect to hold in nominal execution, whereas the second constraint results from perception and proprioception (more on this later). The above **CSP** is not satisfiable: the observed and executed situations are not consistent with the modeled temporal relation representing successful plan execution. This determination can be made in polynomial time (with respect to the number of variables in the **CSP**) with a particular form of inference, called *path consistency* [14.37].

Although convenient for specifying high-level requirements on robot plans, **PA** and **IA** cannot capture metric information. For this, we need metric temporal constraints, which allow to predicate on durations and relative temporal distances between variables. An important metric temporal problem is the temporal constraint satisfaction problem (**TCSP**). As in **PA**, variables represent time points. Constraints represent disjunctions of bounds on the temporal distance between the pairs of time points: given two time points a and b , the constraint

$$a \xrightarrow{[l_1, u_1] \vee [l_2, u_2] \vee \dots [l_n, u_n]} b$$

states that $l_i \leq b - a \leq u_i$, for one or more $i \in \{1 \dots n\}$. A **TCSP** is satisfiable iff at least one disjunct (pair of

Fig. 14.5 The 13 basic qualitative relations in interval algebra. $[l, u]$ indicate metric bounds that can be attached to the basic relations to refine the metric semantics of the relations

inequalities) per constraint holds. Unlike **PA** and **IA**, variables in a **TCSP** are associated with an explicit set of possible assignments of time values, called *domain*. Computing the minimal representation consists of restricting the domains of time points to the smallest intervals of time containing values that satisfy all constraints. A particular restriction of the **TCSP**, called the simple temporal problem (**STP**), has the property that domains are contiguous intervals of time. The condition for remaining in the **STP** fragment of **TCSP** is that constraints have only one disjunct, i. e., are of the form

$$a \xrightarrow{[l,u]} b.$$

Whereas computational problems for the the general **TCSP** are NP-hard, the satisfiability and minimal representation problems for the **STP** are tractable. Both problems are solved by path consistency inference [14.38], and highly optimized algorithms have been developed for the satisfiability and minimal representation problems [14.39, 40].

The semantics of basic **PA** and **IA** can be understood through the use of metric temporal constraints. For instance, the constraint

$$\text{Pick}(\text{Mug}) \{o\} \text{Holding}(\text{Mug}) \quad (14.11)$$

is equivalent to the metric constraints

$$\begin{aligned} \text{Pick}(\text{Mug})^- &\xrightarrow{[1,\infty)} \text{Holding}(\text{Mug})^-, \\ \text{Holding}(\text{Mug})^- &\xrightarrow{[1,\infty)} \text{Pick}(\text{Mug})^+, \end{aligned} \quad (14.12)$$

where $(\cdot)^-$ and $(\cdot)^+$ represent, respectively, the start and end times of the corresponding intervals. Moreover, metric bounds can be used to define a metric extension of **IA** in which we can express high-level relations between intervals with additional metric bounds (Fig. 14.5). For instance, $A\{p[5,13]\}B$ states that interval A should end at least 5 and at most 13 time units before interval B starts. In addition to binary constraints, it is also common practice to define the two unary constraints $\text{Release}[l,u]A$ and $\text{Deadline}[l,u]A$, stating, respectively, that A starts between l and u time units after the origin of time, and that A ends between l and u time units after the origin of time.

Overall, constraint-based temporal calculi can represent both qualitative and metric time. Provided that appropriate fragments of **IA** are used in modeling, the reasoning tasks can be conveniently reduced to path consistency inference in an **STP**. This is an attractive feature for robot reasoning: it provides a means to anchor observations and proprioception in time. In the

example above, the robot must infer from sensing that the relation

$$\text{Pick}(\text{Mug}) \{d^{-1}\} \text{Holding}(\text{Mug}) \quad (14.13)$$

holds. An implementation of this capability can be achieved by representing as time points both observed and planned behavior, and constraining these time points so as to reflect the precise times in which they were observed. Assuming the current time is 20, that the robot started to pick the mug at time 5, and that the gripper reports that it is holding an object between times 10 and 18, the following **STP** models the robot's situation

$$\begin{aligned} &\text{Pick}(\text{Mug}) \{o[1,\infty)[1,\infty)[1,\infty)\} \text{Holding}(\text{Mug}), \\ &\text{Release}[5,5] \text{Pick}(\text{Mug}), \\ &\text{Deadline}[20,20] \text{Pick}(\text{Mug}), \\ &\text{Release}[10,10] \text{Holding}(\text{Mug}), \\ &\text{Deadline}[18,18] \text{Holding}(\text{Mug}). \end{aligned} \quad (14.14)$$

The above **STP** is not satisfiable, reflecting the fact that execution has not gone according to plan. Again, this state of affairs can be ascertained in low-order polynomial time, hence providing a simple mechanism for online fault detection.

The use of temporal constraint reasoning in planning and plan execution goes beyond diagnosing failures. The fact that intervals are grounded on a metric temporal **CSP** (an **STP**) provides a means to maintain knowledge about when actions should be dispatched, and whether they should be delayed to accommodate unexpected contingencies. For instance, we can express that the robot should start moving back to the counter once the mug has been held for at least 3 s with the constraint

$$\begin{aligned} &\text{Holding}(\text{Mug}) \{o[3,\infty)[1,\infty)[1,\infty)\} \\ &\text{Move}(\text{Table}, \text{Counter}). \end{aligned} \quad (14.15)$$

A delay in the start time of the $\text{Holding}(\text{Mug})$ predicate will *propagate* to the start time of the $\text{Move}(\text{Table}, \text{Counter})$ action, progressively pushing its start time into the future until the robot starts holding the mug. Correct propagation of exogenous events is ensured by maintaining in the **STP** the requirements of the plan together with constraints representing when events are observed, when actions are dispatched, and when they terminate. A simple procedure for maintaining these constraints is the following:

- When an action is dispatched at time t , a $\text{Release}[t,t]$ constraint is imposed on the corresponding interval, constraining its start time to the current time.

- The fact that the action is still executing at time $t + m$ is modeled with the constraint $\text{Deadline}[t + m + 1, \infty)$, modeling the fact that the action will end some time in the future.
- When the lower level executive signals at time $t + m + n$ that an action has finished, the constraint $\text{Deadline}[t + m + n, t + m + n]$ is added to the **STP**, thus constraining the action's end time.

Every time a constraint is added, the minimal **STP** is recomputed – that is, the domains of the time points (start and end times of actions and predicates) are updated. In so doing, we ensure that the lower bound of time points representing the start times of actions will always correspond to the earliest admissible time at which actions should be dispatched to the robot's executive layer. This guarantees that execution will uphold all temporal constraints modeled in the temporal **CSP**. These may include additional requirements on the plan, such as specifications regarding necessary orderings of actions, actions that must occur concurrently, and synchronizations with exogenous events.

The computational adequacy of temporal **CSPs** entails that reasoning about temporal models can be performed online during execution. Thus, reasoning about time is a way to enable fault diagnosis, guarantee timely action dispatching, and enforce temporal specifications on robot plans. Mechanisms based on temporal constraint reasoning have been used as a tool for this purpose in many settings involving execution of plans on real physical systems [14.41, 42]. Similar techniques have been used to account for uncontrollable events in plan execution [14.43], inferring context from sensor traces [14.44], and integrated context inference and planning [14.45]. A good overview of the fundamental principles of temporal constraint reasoning underlying these results is given in Dechter's book on constraint processing [14.46].

14.3.3 Reasoning About Space

Spatial **KR** formalisms serve the purpose of specifying desired spatial relations in a scene. As for temporal models, they can be used to make sense of sensor traces, to enforce conditions during plan execution, as well as to drive the planning process itself. Most work has focused on the use of qualitative spatial relations for scene understanding (e.g., in the context of perceptual anchoring [14.47]). Structural pattern recognition, important applications of which can be found in medical domains, employ cognitive vision techniques to match qualitative spatial knowledge (representing a specified structure) to perceived context [14.48, 49]. In many applications, qualitative relations do not belong to a well-defined cal-

culus, rather are tailored to capture specific features (e.g., distance, orientation, and shape) which are useful for pattern specification and recognition in particular applications. As is the case for temporal knowledge, a well-defined spatial calculus is useful because of its provable formal properties – e.g., tractability of specific reasoning problems, expressiveness of the language, and so on. Well-founded spatial calculi permit logical reasoning, and, not surprisingly, they are grounded on similar principles as **PA** and **IA**. We illustrate here these principles and show simple examples of their use in robotic applications.

The main entities of interest in qualitative spatial calculi are objects, or, rather, the regions (or points) of physical space that they occupy. Spatial calculi provide a means to represent the relations among these regions. There exist several well-known and well-studied qualitative calculi. Each of these calculi focuses on one category of spatial concepts – e.g., topology, direction and distance. Region connection calculus (**RCC**) [14.50] is used for representing and reasoning with topological relations. Cardinal direction calculus (**CDC**) [14.51] is an approach based on directional relations. As for temporal calculi, these calculi use the language of constraints to represent spatial properties, and classical constraint-based reasoning techniques like path consistency [14.52] to ascertain consistency.

Of particular interest here is **RCC**, which is grounded on eight spatial relations describing the connectedness of regions: *disconnected* (**DC**), *externally connected* (**EC**), *tangential proper part* (**TPP**), *nontangential proper part* (**NTPP**), *partially overlapping* (**PO**), *equal* (\equiv), and the inverses TPP^{-1} and NTPP^{-1} (Fig. 14.6).

The full algebra deriving from the eight basic **RCC** relations is called **RCC-8**. An important restriction of **RCC-8** is **RCC-5**, obtained by subsuming the relations **DC** and **EC** into one relation, and **NTPP** and **TPP** into another. The satisfiability and minimal **CSP** problems are NP-hard for both **RCC-8** and **RCC-5** – however, these problems are tractable if we restrict the language to the basic relations (as for **IA**), and a large number of tractable fragments of **RCC-8** and **RCC-5** are known [14.53]. A good example of where these properties are useful is in the problem of anchoring modeled relations to observed spatial layouts. This is exemplified in the work by Cohn et al. [14.54] on video sequence analysis, where the problem is to construct qualitative representations of the evolution of spatial relations in video sequences. The qualitative descriptions are obtained online, due to the computational adequacy of the qualitative spatial calculus used (a derivative of **RCC** called **CORE-9**).

Qualitative spatial reasoning can be used, much like qualitative temporal reasoning, to robustify plan execu-

Fig. 14.6 The eight basic qualitative relations in **RCC**

tion. We may, for instance, require that mugs should be placed *on top of* saucers (Mug **NTPP** Saucer). As we have shown for temporal reasoning, the task of verifying the correct state of affairs can be cast to a **CSP** which is guaranteed to be feasible iff the desired spatial layout is observed.

However, note that all we can express with **RCC** constraints are topological relations between objects. **RCC** cannot express notions like *left-of*, *above*, and so on, as the only assumption made on variables is that they are convex regions of space. Conversely, rectangle algebra (**RA**) [14.55] expresses more than topological relations – at the cost of assuming that objects have a particular shape. Specifically, **RA** is an extension of **IA** to two dimensions. Its variables thus represent axis-parallel rectangles, and relations are pairs of **IA** relations, one for each axis.

RA can be augmented, like **IA**, with metric bounds. The resulting calculus, called **ARA**⁺ [14.56], subsumes both topology and cardinal relations. For in-

stance (Fig. 14.7), the relation

$$B \langle p[5, 13], p \rangle A \quad (14.16)$$

states that B precedes A in both the x and y axes, and that the distance along the x axis between A and B should be at least 5 and at most 13. The **ARA**⁺ relation subsumes the qualitative relation *A is Northeast of B*, as well as the **RCC** relation $A\{DC\}B$. Note that rectangular regions are compatible with the representation of segmented objects in most off-the-shelf perception modules. This property facilitates the process of going from sensor data to symbols. Toward this aim, **ARA**⁺ provides the unary constraints $At[l_1, u_1][l_2, u_2][l_3, u_3][l_4, u_4]$ and $Size[l_1, u_1][l_2, u_2][l_3, u_3][l_4, u_4]$. The first constraint bounds the length of the sides of a rectangle, while the second bounds the placement of a rectangle in 2-D space. Note that the At constraint performs a similar function to the Release and Deadline constraints used in the metric extension of **IA**, which denote specified or perceived absolute placements in time of intervals. It is thus intuitive to see how the At constraint can be implemented with Release and Deadline constraints in the augmented **IA CSPs** used to represent the projections of rectangles on the two axes.

We can employ **ARA**⁺ constraints to represent desired placements of objects, both in qualitative and metric terms. For instance, the specification of a well-set table for our waiter robot could be

$$\begin{aligned} & \text{Fork } \langle d[5, +\infty][5, +\infty], \\ & \quad d[5, +\infty][5, +\infty] \rangle \text{ Table}, \\ & \text{Knife } \langle d[5, +\infty][5, +\infty], \\ & \quad d[5, +\infty][5, +\infty] \rangle \text{ Table}, \\ & \text{Fork } \langle p, d \rangle \text{ Mug}, \\ & \text{Mug } \langle p, d \rangle \text{ Knife}, \\ & \text{Mug } \text{Size}[8, 8][8, 8], \\ & \text{Fork } \text{Size}[2, 2][15, 15], \\ & \text{Knife } \text{Size}[2, 2][15, 15], \end{aligned} \quad (14.17)$$

Fig. 14.7 The **ARA**⁺ relation $B\langle p[5, 13], p \rangle A$, which subsumes **RCC** relation $A\{DC\}B$ and **CDC** relation *A Northeast of B*

that is, forks and knives should be at least 5 cm from the edge of the table, forks should be located on the left of mugs and knives on the right, the size of forks and knives is $2 \times 15 \text{ cm}^2$, and the size of mugs is $8 \times 8 \text{ cm}^2$.

The above relations can be maintained, much like we have illustrated for temporal reasoning, in a lower-level metric constraint-based representation – in this case, consisting of two STPs, one for each axis of the reference frame. It has been shown [14.56] that these two STPs are satisfiable iff the ARA^+ CSP is satisfiable, and that the minimal STPs contain all the admissible placements of objects. The minimal STPs can thus be used to extract an admissible placement of the objects in the scene. Technically, this is done by *hallucinating* the objects that are to be placed in the scene, that is, representing both observed objects and those that are intended to be placed into the scene in the spatial CSP. In the example above, supposing the robot must place the mug on a table which already has a fork and a knife on it, the hallucinated object is the mug, while the fork and knife would be constrained by At constraints representing their observed locations. The bounds of all variables in the minimal STPs represent all the admissible placements of the objects. Those of the fork and knife will not have been refined in the minimal representation, as they were already fixed by the At constraints resulting from observation; conversely, the bounds of the Mug rectangle are refined in the minimal representation to contain only those points that are admissible wrt. the other constraints in the spatial CSP.

So far, we have shown how employing constraint-based temporal and spatial KR formalisms allows to cast the problem of fault detection to a tractable problem that can be solved online. Another important aspect of plan execution that is facilitated by these representations is fault identification and repair [14.57]. It is easy to see why an explicit representation formulated in terms of constraints facilitates these tasks: suppose that the fork and knife are placed on the table correctly from the qualitative point of view – i.e., the fork is left of the knife – but that they are only 5 cm apart. The resulting spatial CSP would not be satisfiable, as it would be impossible to fit the mug (whose bounding box is $8 \times 8 \text{ cm}^2$) between the two pieces of cutlery, as prescribed by constraints $(\text{Fork}(p, d) \text{Mug})$ and $(\text{Mug}(p, d) \text{Knife})$. The spatial CSP can be used at this point as a tool to perform *culprit analysis*: the same CSP without the At constraint modeling the observed placement of the fork represents the situation in which we assume that the fork can be moved; if this CSP is satisfiable, then we know that replacing the fork is a way to achieve a well-set table.

Spatial reasoning has not received as much attention as temporal reasoning in the context of robotic applications. The AI and Robotics research communities are, however, quickly clustering around this important topic. Spatial calculi are a well studied topic in AI, albeit with less applications in robotics than temporal reasoning. As robots become more competent in manipulation and navigation tasks, the issue of representing and enforcing high-level requirements on space begins to come to the fore. As always, it is the combination of epistemological and computational adequacy of significant fragments of spatial KR formalisms that makes them useful in robot applications. Indeed, the potential of qualitative and metric spatial reasoning goes beyond planning and plan execution, with active research directions in human–robot interaction [14.58–60] and object search [14.61].

14.3.4 Reasoning About Multiple KR Formalisms

Despite their simplicity, the examples we have used to illustrate the basic concepts of temporal and spatial reasoning point to the fact that reasoning about action, time, space, and any other knowledge possessed by the robot must occur jointly. For instance, the decision to place the mug on the table may depend on the spatial layout of other objects on the table, or on whether there is a more urgent task to be carried out before doing so. It is easy to see that even this simple task cannot ignore kinematics and geometric constraints, which may call for approaching the table from a different side, or to move another object before placing the mug. Recent work in integrated task and motion planning is a response to the need for integrating these forms of reasoning into planning. Today, this is very much seen as the next big challenge, and consistent research results in this specific area of hybrid reasoning are closing the gap between classical planning and real robotic applications [14.62–67].

We argue, however, that kinematics and geometric constraints are only two of the important types of knowledge necessary for achieving competent robot behavior. Comparatively less work exists in integrating other types of knowledge. DL reasoning has been employed to generate high-level plans [14.68], to refine planning domains [14.69], and Galindo et al. [14.70] show how to enhance the task planning process with spatial and ontological models. The largest volume of work in integrating diverse forms of reasoning into planning focuses on integrating planning, temporal, and resource reasoning – e.g., planning with metric temporal reasoning [14.71], qualitative temporal models [14.44], combined qualitative and metric temporal

reasoning [14.72], and resource scheduling [14.73–75].

Although these advancements contribute to widening the expressive power of models for robot reasoning, they do not suggest general methods for jointly reasoning about heterogeneous KR formalisms. As noted earlier, the types of knowledge a robot should possess ultimately depend on the application, which makes this an important basic research question. A few examples pointing in the direction of general solutions do exist, although work in the area is sparse. These include planning modulo theories [14.76], an extension of satisfiability modulo theories (SMTs) [14.77], which enrich classical planning models with semantics belonging to arbitrary first order theories. SMTs themselves are an example of general hybridization scheme, and have been employed in a robotic context by Nedunuri et al. [14.78] to enforce metric requirements on motion and manipulation tasks. The approach known in the literature as meta-constraint reasoning is similar in structure to SMTs, but is grounded on the more general notion of CSP. Meta-constraint reasoning has been used to develop solvers for highly expressive planning domains that include qualitative and metric time, resources, and logical constraints [14.79]. In the context of robotic applications, the approach has been used for online planning with qualitative and metric time, spatial relations in ARA⁺ and resources [14.57], as well as for online configuration planning for multirobot systems [14.80].

14.3.5 Knowledge Representation Systems for Robots

In autonomous robot control systems, the kinds of information that we have discussed in the previous subsections are not only represented and reasoned about but also used subsymbolically for generating perception-guided activity. For example, some information such as the appearance and poses of the objects on the table might be generated by the perception system of the robot through the interpretation of sensor data. Other information such as the position of the robot in the environment might be estimated using state estimation algorithms and stored in dedicated data structures. Also, symbolic action descriptions have to be translated into low-level parameterizations of control routines in order to generate behavior and cause effects.

These aspects of embodying abstract and symbolic reasoning in robots are at least partly addressed by system-level research on KR and reasoning for robots. The resulting systems serve as integrated question-answering components in a robot's control program that

gather information from different sources and employ a range of inference methods for controlling and parameterizing control routines.

Examples of recent systems include the ontology-based unified robot knowledge (OUR-K) framework [14.81], mostly used for navigation actions, the ORO system [14.82] that focuses on knowledge for human–robot interaction and dialog grounding, and the KnowRob system [14.83] providing deep knowledge for robotic manipulation tasks. The semantic layer [14.84] of the PEIS Ecology [14.85] serves both autonomous robots and ambient intelligent environments. In the Ke Jia project [14.86], Answer Set Programming is used as representation for integrating KR, natural language processing, task planning and motion planning on a mobile platform. Also classical cognitive architectures such as Soar [14.87] and ACT-R also integrate modules for storing knowledge [14.88] with inference capabilities, but have only rarely been used on robots [14.89].

One field that has seen much progress in the past years is the creation and representation of environment models, often termed *semantic maps*. Advances in object recognition allowed to detect and perceptually interpret single objects in environments, which enables robots to store higher level semantic information about them in their respective maps. The term *semantic* is used for a range of different interpretation capabilities – from a mere segmentation and categorization of the environment into different region types to the segmentation of objects, their categorization, and the interpretation of their properties [14.90], or from the co-occurrence of objects in scenes [14.91] up to environment representations in description logics [14.92], from statistical relational environment models [14.93] to an embedding of spatial information into an encyclopedic and common-sense knowledge base [14.94]. Many of the reasoning tasks that we have discussed in Sect. 14.3.3 have implicitly assumed expressive semantic maps that can make symbolic place descriptions such as *on the table* or *in the cupboard* effective.

Knowledge representation aspects also become increasingly important for the instruction of robots with natural language as well as for human–robot interaction. For understanding directives involving objects in the environment [14.95] and for following spoken directions [14.96–99], a robot might have to ground the words it hears or reads into its percepts and actions. The natural-language text may be the result of direct interaction with a human, but can also be obtained from resources on the Web, for example, for mining object locality knowledge [14.100] or extracting task instructions from websites [14.101] ( VIDEO 705).

Web-enabled robotics is another branch of robotics that has recently become increasingly important. Modern robot control systems use the worldwide web as an information resource [14.102], for sharing knowl-

edge and skills [14.103], for telepresence applications [14.104], to employ web services [14.105], and to use computational resources provided through the web [14.106] (📺 VIDEO 706).

14.4 Plan-Based Robot Control

Plan-based control is an information processing approach for controlling autonomous robots that aims at making robot control systems more general – in at least three respects. First, it enables robots to successfully carry out multiple, diverse, and possibly interfering tasks. Second, it can improve the course of action by adapting the control software for the respective execution context. Third, plan-based control can enable robots to perform novel tasks without requiring the collection of extensive experience.

In the plan-based approach, robots generate actions and behavior by synthesizing, maintaining, and executing plans, where plans are robot control programs that a robot cannot only execute but also reason about and manipulate [14.107]. Thus plan-based controllers can manage and adapt plans in order to better achieve complex and changing tasks [14.108]. The use of plans enables robots to flexibly interleave complex and interacting tasks, exploit opportunities, quickly plan their courses of action, and, if necessary, revise their intended activities.

Plans in plan-based control have two roles. They are (1) executable prescriptions that can be interpreted by the robot to generate behavior in order to accomplish its jobs and (2) representations that can be synthesized and revised by the robot to meet the robot's criterion of utility. Besides having means for representing and generating plans, plan-based controllers are also equipped with tools that enable computational processes to (1) predict what might happen when a robot controller gets executed and return the result as an execution scenario, (2) infer what might be wrong with a robot controller given an execution scenario, and (3) perform complex revisions on robot controllers.

In most general terms robot planning can be considered to be the automatic generation, refinement, revision, and optimization of robot plans [14.107]. As a computational problem it can be formulated as follows: given an abstract plan P and a description of the current situation, find an executable realization Q that maximizes some objective function V . In this problem formulation, an abstract plan might be to go shopping and to clean up the apartment, to win a robot soccer game, to monitor the traffic in a particular area using an autonomous helicopter, or, for a museum tour-

guide robot, to inform and entertain the visitors of the museum.

Robot planning algorithms aim at finding appropriate plans by hypothesizing possible courses of action and predicting what could happen when the plans get executed. Based on these predictions, the robot decides whether the plan will meet its objectives.

In the remainder of this subsection we will first discuss conceptual models underlying robot planning and the representation of robot plans. We will then talk about the automated synthesis of robot plans and finally discuss mechanisms for revising plans and optimizing plans based on experience.

14.4.1 Models of Plan-Based Control

The generation of plans and the prediction of what will happen is based on models of the robot, its actions, and the world. The most commonly used models are state-transition systems (also called discrete-event systems or problem spaces) [14.27].

Using state-transition systems, the behavior and the effects of robot activity can be represented as a triple $\Sigma = \langle S, A, \gamma \rangle$, where:

- $S = \{s_1, s_2, \dots\}$ is a set of states
- $A = \{a_1, a_2, \dots\}$ is a set of actions
- $\gamma: S \times A \rightarrow S$ is a state-transition function.

Thus, the action repertoire of a robot can be stated as a graph where the nodes represent the states of the environment and links of the form

$$s_i \xrightarrow{A} s_j$$

represent the fact that the state s_i can be transformed into the state s_j by the robot executing action A .

Imagine a robot has to stack three different objects, e.g., a cup, a saucer, and a set. In the initial state, all objects are placed on a table surface. The robot can pick an object (provided that there is no other object on top of it) and can place it either on the surface or on top of another object (provided, again, that there is nothing already on top of it). If we further assume that each object can be placed on all other objects, and that only a single

object can be moved at a time (and not a stack of two of them), then we get the state space depicted in Fig. 14.8.

The state-transition model abstracts away aspects of robot activity such as the structure of actions and the events, behavior, and effects that are caused during action execution. Actions are considered to cause atomic state transitions.

Even with these abstractions, a number of variations of planning problems are investigated. These variations result from different trade-offs one can make with respect to the computational complexity of the planning problem, the strength of assumptions one makes about the capabilities of the robot, and the realism with which one wants to represent the behavior of the robot and the effects of its actions.

An important subclass of state-transition models are the ones that characterize action by specifying their preconditions and effects [14.25, 109, 110]. Preconditions state the conditions under which the respective action is executable and has the specified effects. The effects represent how the world changes when the action is executed.

If these models are stated as axioms in a logical representation language (Sect. 14.2) planning methods can

be particularly powerful: they can compute sequences or partially ordered sets of actions that are provably working plans from the logical point of view. This means that planning algorithms can find plans that are guaranteed to transform any state satisfying a given state description into a state that satisfies a given goal, if such a plan exists. Unfortunately, in many robot applications action models that are axiomatized this way are too unrealistic.

Many extensions of the state-transition model deal with providing the expressive power needed to state action models more realistically. The first one extends the state-transition model by allowing state transitions to be caused by a combination of an action and an event ($\gamma: S \times A \times E \rightarrow S$) rather than the action alone. This modification allows us to represent action failures by stating that a failure event occurs while the action is executed. It also allows us to approximate environments that are dynamically changing. The second extension is to change the state transition function such that it maps into a subset of states rather than a single state ($\gamma: S \times A \rightarrow 2^S$). This modification allows the robot to reason through the nondeterminism that can often not be avoided when autonomous robots perform realis-

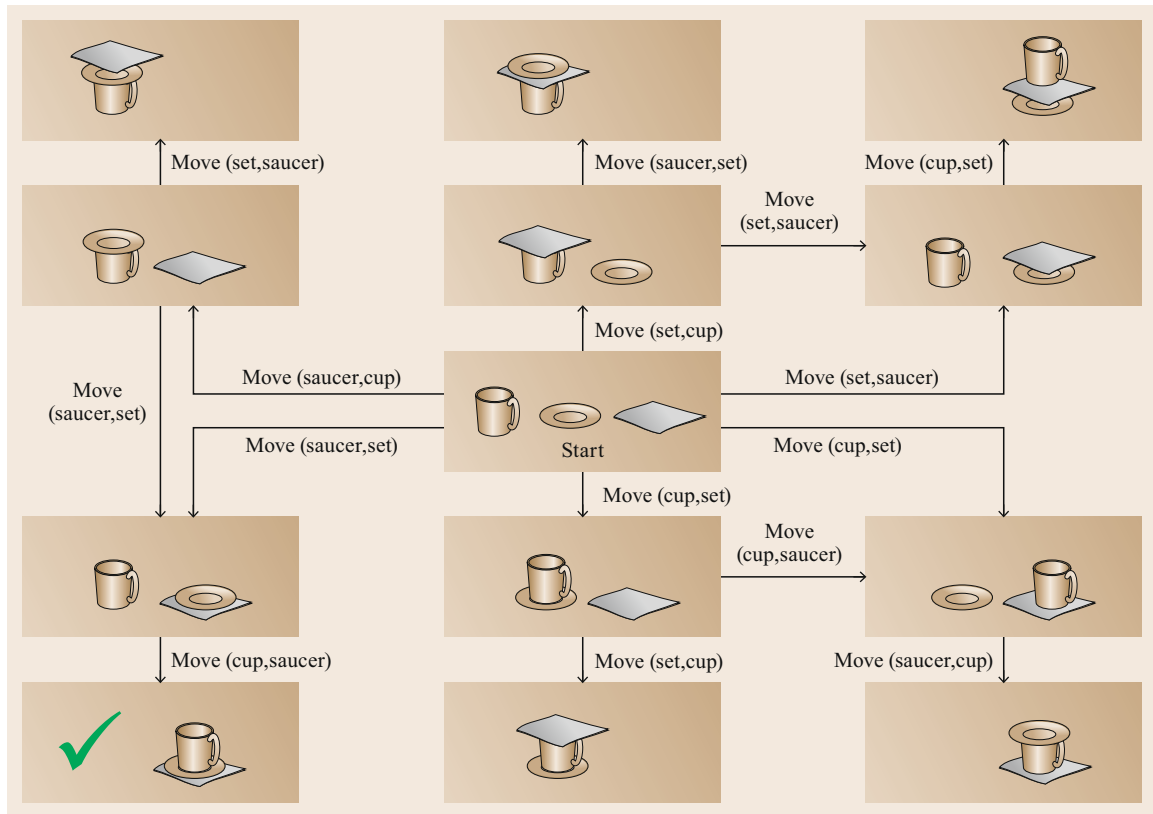

Fig. 14.8 Example: problem space for stacking three objects

tic activities. Other researchers extend models used for plan-based control by including aspects that allow the robot to reason about its resources, geometric aspects of manipulation actions [14.24, 111], sensing actions, and so on.

Besides the state-transition model researchers also use hybrid system models to reason about robot activities [14.112–114]. In the hybrid system model the action repertoires of robots are specified as continuous variable dynamical systems with a phased operation. Within each phase, called control mode, the system evolves continuously according to the dynamical law of that mode, called continuous flow. Thus, the state of the hybrid system can be thought of as a pair – the control mode and the continuous state. The control mode identifies a flow, and the continuous flow identifies a position in it. Also associated with each control mode are so-called jump conditions, specifying the conditions that the discrete state and the continuous state together must satisfy to enable a transition to another control mode. The transitions can cause abrupt changes of the discrete as well as the continuous state. The jump relation specifies the valid settings of the system variables that might occur during a jump. Then, until the next transition, the continuous state evolves according to the flow identified by the new control mode.

The advantage of a hybrid-system-based conceptualization over state-based ones is that hybrid systems can adequately model concurrent processes with interfering continuous effects. They also allow for discrete changes in process parameterization, which we need to model the activation, deactivation, and reparameterization of control processes through concurrent reactive plans (Sect. 14.4.2). In addition, hybrid system based conceptualizations can model the procedural meaning of waiting for and reacting to asynchronous events.

While the increased expressive power allows us to model the behavior that today’s autonomous manipulation robots generate much more faithfully, the models are also in most cases too complex to completely synthesize action plans from primitive actions. Many of the modelling issues to be addressed in the intersection between action planning and control are discussed in [14.115, 116].

14.4.2 Representation of Plans

When the robot is performing its activity, it is under the control of a plan. The most common forms of action plans in autonomous robot control are:

- State-transition plans, totally or partially ordered sets of atomic actions.

- Policies, mappings from (perceived) environment states to actions.
- Reactive plans that specify how the robot is to respond to sensory events and execution failures in order to accomplish its jobs.

State-Transition Plans

Robot action plans that are generated according to the state-transition model are ordered sets of actions, often called plan steps. The assumptions of the state-transition model, in particular that plan steps are atomic and their execution can be abstracted away, are not satisfied in many robot applications. To execute plan steps successfully, actions have to include subactions such as detecting the object to be fetched in a scene or detecting that the object has been successfully grasped before lifting the arm. As autonomous robot activity is far from perfect, the robot might not be able to generate the necessary execution events or it can generate the events but fails to achieve the desired effects. For example, an object might slip out of the robot’s hand after grasping it.

As a consequence, state-transition plans can often only serve as guidelines for generating robust and flexible robot behavior [14.117]. To close the gap to low-level robot control, researchers have proposed multilayer software architectures for autonomous robot activity, in particular 3T (3-tiered) architectures [14.118] (Chap. 12). 3T architectures run planning and execution at different software layers and different time scales where a sequencing layer synchronizes between both layers. Each layer uses a different form of plan or behavior specification language. The planning layer typically uses a problem space plan, whereas the execution layer employs feedback control routines that can be activated and deactivated. The intermediate layer typically uses a simple form of a reactive plan language (see below). Even though 3T architectures have been shown to produce competent activity in some application domains, there remain important issues to be addressed for more complex applications. One of them is that the behavior generated by the sequencing layer might deviate substantially from the action model used for planning, which might cause plans not to work as expected by the action models used by the planning component. As the planning layer abstracts away from control structures, it also lacks the expressiveness to specify robust and flexible behavior.

MDP Policies

A second category of plans are policies, which are mappings from discretized robot states into robot actions. Such policies are computed as solutions of Markov decision problems (Sect. 14.2.2). The policies computed

by MDPs aim at robustness and optimizing the average performance. They are less appropriate when the consequences of decisions are not in the near future. The decision of how to grasp an object might considerably affect the ease with which the object can be placed later in the activity episode. Extensions of MDP policies such as the combination of programming and reinforcement learning [14.119, 120] and the structuring of policies with so-called options [14.121, 122] partly address these issues.

Concurrent Reactive Plan Languages

Concurrent reactive plan languages are the result of applying programming language design methods to the specification of robot behavior. Concurrent reactive plans specify how the robot is to respond to events, including perception and failure events, in order to achieve its goals [14.123]. Such plan languages offer rich sets of control structures that support the structuring and transparent synchronization and monitoring of concurrent control processes, the detection and recovery from execution failures, the context-dependent execution of subplans, the prompt reaction to asynchronous events, and data structures for the descriptions of objects to be manipulated [14.124, 125]. Some reactive plan languages also incorporate explicit representations of the beliefs, goals, and intentions of the robot [14.126–128] and even provide powerful reasoning mechanisms to adapt the plan execution to the respective situation context [14.129].

While concurrent reactive plan languages enable robots to accomplish their tasks competently, they are too expressive for automatically generating robust, flexible high-performance plans from first principles. They typically require the use of plan libraries and transformational planning techniques to deal with the computational complexity caused by the expressiveness of the plan languages (Sect. 14.4.4).

14.4.3 Generating Robot Action Plans

The most common form of reasoning performed on plans is the synthesis of plans for given problems. In general, planning is concerned with reasoning about intended courses of action before executing them in order to avoid failures in achieving given goals, to prevent undesired side effects, or to improve the performance of the robot in accomplishing its goals.

There are many different variants of planning problems, categories of plans that can be generated, and methods that can be applied to planning problems. Comprehensive overviews can be found in textbooks [14.4, 27] and overview articles [14.130, 131]. A wide range of the planning problems is ad-

ressed within an international AI planning competition (IPC) [14.132] using standardized problem specification languages [14.109, 110]. Several implementations of planning algorithms participating in this competition are available as open-source software.

In planning for state-transition, the task of the planning system is to find an ordered set of actions that transform any state satisfying the initial state description into a state satisfying the given goals.

The first class of planning systems are systems that enumerate the states that can be reached by prefixes (or suffixes) of hypothetical action sequences until a goal state is reached. Planning systems that fall into this category include the STRIPS planning algorithm [14.25] and newer and more efficient algorithms such as the FF (fast forward) planning algorithm [14.133] as well as various variants of these algorithms.

Another class of algorithms enumerates abstract plans that represent sets of plans. The idea underlying this approach is that by reasoning about an abstract plan, the planning algorithm can compactly reason about different plan instances at the same time by reasoning about their common causal structure. For example, a partial order plan represents all possible completions of the plan. The POP (partial-order planning) algorithms is a family of algorithms that is primarily used for teaching action planning [14.130] while GraphPlan [14.134] is an algorithm that is designed for planning process efficiency [14.131].

The algorithms above are domain independent: they compute plans by analyzing whether preconditions of plan steps are achieved through the effects of prior actions using general algorithms. In contrast, domain-dependent planners use domain knowledge to constrain and prune the search space to be explored in a planning process. An example of such domain knowledge is that stacks of objects are built bottom up. Domain-dependent planners are often much more efficient than their domain-independent counterparts. Examples of domain-dependent planners are the TL- (temporal logic) [14.135] and the TAL planners [14.19].

Another category of planners that are designed to deal with more complex planning problems are HTN (hierarchical task network) planners. HTN planners are equipped with libraries of plan schemata that specify how abstract plan steps can be decomposed into more complex subplans. Examples of such planners are the SHOP planners [14.136] and extensions thereof that are combined with description logics and applied to autonomous robot control [14.69].

The planning approaches above generate plans that have similar expressiveness in terms of the behavior they can specify. The planners mainly differ with re-

spect to the size of the planning problems they can handle and their efficiency in solving planning problems.

14.4.4 Revising and Improving Plans

Another dimension that robot action planning methods can be scaled along is the expressiveness of the plans they generate in terms of specifying competent robot behavior. A subclass of planning methods that is suitable for generating concurrent reactive plans is *transformational planning*.

The underlying idea of transformational planning is to paste together plans from libraries of plan schemata and revise them for the specified task [14.137] rather than creating completely new plans from scratch. Transformational planning has also been referred to as *plan repair* or *plan debugging* [14.138, 139] and is often performed within a *generate-test-debug* control strategy [14.140]. Plan transformation is a promising approach in applications where default plans that have a substantial chance of being successful can be constructed easily, tested by projecting them, analyzed with respect to their expected execution failures, and where failures can be used to index the appropriate plan revisions.

Transformational planning subsumes classical planning methods such as partial-order planning in the sense that the operations of the POP algorithms can be simply expressed as transformations. In addition to the transformations that correspond to classical planning, transformational planning typically employs collections of transformations including domain-specific ones, heuristic transformations, and transformations for plan optimization [14.141]. In cases where the planners employ transformations that cannot be guaranteed to work, they rely on powerful plan projection methods for testing the generated plan hypotheses [14.142].

Transformational planning is a promising approach for autonomous robots performing complex manipulation tasks because it makes it easy for programmers to specify how plans should be modified to avoid certain expected behavior flaws. For example, a transformation could tell the robot to stack items in order to transport them more efficiently subject to additional constraints such as that it should not stack too many items because it might drop them. Or, it might stack one kind of object on another one but not vice versa – typically it is safe to stack cups on plates but not plates on cups.

Transformational planning can also effectively facilitate the learning not only of plans [14.139] but also of planning capabilities by learning for a particular robot and environment what the robot can stack and carry and what not.

14.4.5 Other Reasoning Methods

There are a number of other reasoning methods that plan-based robot control needs to employ in order to produce competent object manipulation capabilities [14.143]. One of the main reasons is that the tasks and subtasks that a robot is to perform are typically underspecified: the robot might be asked to fetch the screwdriver from the table but when it gets there are several different screwdrivers. Or, the robot might be asked to crack an egg and has to decide where to crack it, where to put the yolk and egg white, what to do with the shell, etc. When fetching objects, it has to reason about abstract states such as visibility and reachability of objects. We can only give a couple of examples here.

The first reasoning problem is that of *object identity resolution*, the inference task of deciding whether two internal representations refer to the same object in the real world. When receiving the command to pick up the red cup from the table, the robot must make at some point the decision that a data structure returned by the robot's perception system and the language description refer to the same object. Only by making this inference, the robot is able to infer that it can achieve the given task by picking up a particular object that it sees. In logic-based representations this problem is even harder because symbols used in the planning problem specification *denote* objects in the outside world. In this setting the problem of object identity resolution problem becomes the *symbol grounding problem* [14.1], i. e., the problem to determine *the right* or, at least, *the most likely* object in a given environment for each constant and each definite description in the logical representation. The most powerful inference methods to reason about object identity resolution are first-order probabilistic reasoning mechanisms as described in [14.144].

Other important inference methods are needed to model some predicates used in the activity models more realistically. Predicates that deserve such special treatment include *visibility* and *reachability*. For example, the Asymov planner [14.111] reasons about action preconditions that include reachability conditions and tests reachability through the existence of motion plans. Other planning systems reason about the next best views that a robot should take in order to perform complex perception tasks. Sophisticated action planners that include action and motion planning employing more general geometric reasoning capabilities can be found in [14.66]. Cognition-enabled plans employ such reasoning methods in order to parameterize actions with respect to the effects that should be achieved and avoided [14.62].

14.5 Conclusions and Further Reading

The aim of this chapter was, first, to motivate the purpose and benefit of employing general reasoning methods in robot control; second, to sketch some of the generic reasoning methods from AI that are well-understood, available, and most likely of use on a robot; and third, to go into plan-based robot control in some more detail, as it is a particularly obvious form of employing reasoning to the end of improving robot action.

Yet, the chapter has only sketched the tip of an iceberg. Employing symbolic reasoning in an autonomous mobile robot requires to have and update on the robot a symbolic model of the world, or at least of that part of the world which is relevant for the current task – but who knows beforehand exactly what is and what isn't relevant for some task? It therefore requires to be able to interpret the current sensor data stream on a semantic level to transform it into a symbolic description in terms of categories that are meaningful in the KR. Assuming that it is not practical to equip a robot with all knowledge that may likely be relevant for each and every situation it may find itself in, it requires some form of learning, generalization, and/or the ability to look up unknown knowledge from available sources. These and some more requirements that are needed for practically using AI reasoning methods on a robot cannot be fulfilled completely based on current state-of-the-art AI methods and technology; as a consequence, currently existing robot prototypes employing AI reasoning methods in their control systems are limited in terms of generality and adaptability.

It is no recent insight that employing AI reasoning methods on robots is both a chance and a challenge. In fact some of the early influential work in AI was driven by the idea of designing integrated *reasoning robots*, such as SHAKEY [14.145] (📺 VIDEO 704); as

a consequence, early AI textbooks like [14.146] would naturally include robotics as a target field for using AI reasoning methods. The field of AI has since focused on applications other than Robotics. Recent efforts in integrating reasoning systems with autonomous robots have done much to bring the original robot-inspired vision back into focus, as witnessed by series of workshops on *AI-Based Robotics* (e.g., IROS 2013) or *AI and Robotics* (AAAI 2014). It is exactly the family of challenges and chances that this chapter is about that is discussed at these events.

14.5.1 Further Reading

For a more complete coverage of the generic methods described here, as well as the rest of AI, we refer to AI textbooks, of which the one by Russell and Norvig [14.4] is comprehensive and currently most widely used. Among the sources for first-hand material, let us mention the two journals *Artificial Intelligence* and *Journal of Artificial Intelligence Research* (JAIR) [14.147], which both cover well the topics addressed here. The main international conference in the field is IJCAI (*International Joint Conference on Artificial Intelligence*); ECAI (*European Conference on Artificial Intelligence* [14.148]) and AAAI (*Association for the Advancement of Artificial Intelligence Conference on Artificial Intelligence* [14.149]) are other major international symposia on Artificial Intelligence in general. Regarding planning in particular, ICAPS (*International Conference on Automated Planning and Scheduling* [14.150]) is the main international conference.

Reference [14.151] reviews about the same topic as this chapter, but structures it differently along the notion of *deliberation functions*.

15. Robot Learning

Jan Peters, Daniel D. Lee, Jens Kober, Duy Nguyen-Tuong, J. Andrew Bagnell, Stefan Schaal

Machine learning offers to robotics a framework and set of tools for the design of sophisticated and hard-to-engineer behaviors; conversely, the challenges of robotic problems provide both inspiration, impact, and validation for developments in robot learning. The relationship between disciplines has sufficient promise to be likened to that between physics and mathematics. In this chapter, we attempt to strengthen the links between the two research communities by providing a survey of work in robot learning for learning control and behavior generation in robots. We highlight both key challenges in robot learning as well as notable successes. We discuss how contributions tamed the complexity of the domain and study the role of algorithms, representations, and prior knowledge in achieving these successes. As a result, a particular focus of our chapter lies on model learning for control and robot reinforcement learning. We demonstrate how machine learning approaches may be profitably applied, and we note throughout open questions and the tremendous potential for future research.

In the future, robots will be part of daily life in human society, providing assistance in many areas ranging from clinical applications, education and care giving, to normal household environments, disaster scenarios, and space exploration [15.1]. Robots will no longer be used to only execute the same task thousands of times, but rather they will be faced with thousands of different tasks that rarely repeat in an ever changing en-

vironment [15.2]. It will be difficult to preprogram all possible tasks and scenarios in such robots, and robots will need to be able to learn by themselves or with the help of humans. They will need to automatically adjust to stochastic and dynamic environments, as well as to changes due to wear and tear. Machine learning will be necessary to achieve this high degree of autonomy and enabling future robots to perceive and act in the world.

15.1 What Is Robot Learning

Robot learning consists of a multitude of machine learning approaches in the context of robotics. The type of the learning problem is usually characterized by the type of feedback, the process of data generation, and the type of data. At the same time, the type of data will determine the robot learning approach which actually can be employed. While the field of robot learning includes a huge number of topics ranging from learning in perception, state abstraction, decision making, and probabilistic techniques in robotics [15.3–5], this chapter focuses on issues of learning action generation and control. As indicated in Fig. 15.1, we explain robot learning using the two key ingredients: (i) the setting in terms of data and feedback, and (ii) the learning approach.

15.1.1 Robot Learning Approaches

In this chapter, we will focus on the core robot learning approaches capable of learning action generation

and control. Particularly, we will be focusing on techniques of *model learning* and *reinforcement learning* (RL). (Note that we omit imitation learning by behavioral cloning as Chap. 75 deals with it extensively.) These methods have enabled real-time learning in complex robot systems such as helicopters, legged robots, anthropomorphic arms, and humanoid robots. We first discuss some broader issues of learning control before reviewing technical details and the related literature.

Learning Models for Control

Models are among the most essential tools in robotics, and it is widely believed that intelligent mammals also rely on internal models in order to generate their actions. A model describes essential predictive information about the behavior of the environment and the influence of an agent on this environment. While classical robotics relies on manually generated models based on human insights into physics, future autonomous

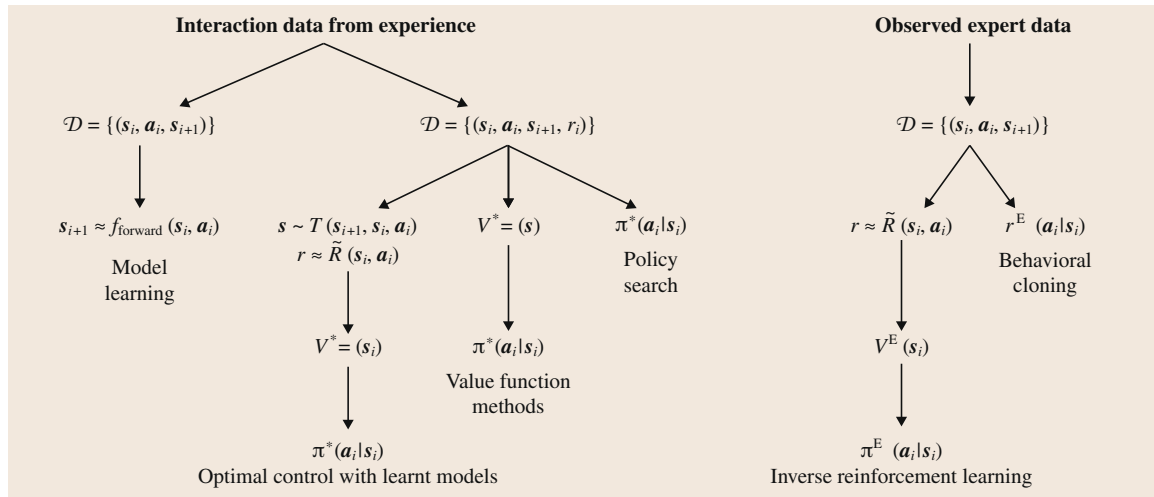

Fig. 15.1 The main branches of robot learning for action generation and control can be characterized both in terms of the available data \mathcal{D} and the employed approach that learns from the data. A key distinction for data sets is whether they were generated from observed expert's demonstration or the robot's embodied experience. Data sets generically include samples i that consist at least of states s_i , actions a_i , and next states s_{i+1} . However, in many cases, a quality assessment in form of a reward r_i is available as feedback. The branches in the tree illustrate the core robot learning problems considered here. Model learning generate a model $T(s_{i+1}, s_i, a_i)$ from data. Reinforcement learning approaches require a reward in order to obtain an optimal policy π^* . Model-based methods usually learn a model from which they subsequently construct an optimal value function and policy. Model-free methods either learn value functions from data without model knowledge to construct a policy while policy search methods optimize the policy directly based on the interaction data. Expert data allows for reproducing observed behavior π^E . Two branches have had a particular importance in robot learning: imitation learning by behavioral cloning can be treated by supervised learning and is discussed in detail in Chap. 74. Imitation learning by inverse RL reconstructs the reward function of the expert and uses reinforcement learning approaches to re-construct the expert's policy (This figure was inspired by [15.6])

robots need to be able to automatically generate models from information which is extracted from the data streams accessible to the robot. Machine learning approaches in generating these models will also need to be adapted to the control architectures for which they are intended. Such model learning for control will be discussed in Sect. 15.2.

Planning with Reinforcement Learning

Planning motor behaviors and optimizing them with respect to some criteria is part of every motor skill. Reinforcement learning offers one of the most general frameworks to address these issues. In essence, it assumes that the goal or intent of a movement is represented in terms of an optimization or reward criterion, such that learning algorithms can fill in the often nontrivial details of the plan. While RL has wide area of application in many domains ranging from computer games to elevator scheduling [15.7], its application to high-dimensional physical systems with continuous state–action spaces requires often dedicated approaches, algorithms, representations, and prior knowledge. An important issue will also be the choice between model-based and model-free algorithms, as well as between value function-based and policy search methods. Reinforcement learning’s different branches are indicated in Fig. 15.1 and will be discussed in Sect. 15.3.

Learning from Demonstration with Inverse Reinforcement Learning

Learning a skill starting from scratch with a complex robot system is often infeasible or extremely time consuming. Taking inspiration from child teaching techniques, learning from demonstration has become a very popular tool to endow a robot with some initial reasonable performance, from which further learning can progress more rapidly. As another chapter in this handbook will address learning from demonstration in more detail, we also discuss a particular subclass of learning from demonstration, i. e., using inverse RL (the two most relevant classes of imitation learning are indicated in Fig. 15.1). Inverse RL addresses how to extract a suitable cost function from observed behavior, an idea going back to *Kalman* [15.8]. Algorithms for inverse RL are tightly coupled to RL which we can only briefly discuss in Sect. 15.3.6, *Curse of Goal Specification*, but they are also discussed in Sect. 75.4.3.

As learning has found many applications in robotics, this chapter can only scratch the surface and extensions of several sections can be found in [15.9, 10]. By focusing on the key approaches for teaching a robot new abilities, we nevertheless hope to give a concise overview.

15.1.2 Robot Learning Settings

The setting of robot learning methods is determined by the data. Data can either be obtained from an expert or generated by interaction with the system. Often data needs to be reproduced accurately (as e.g., for model learning or imitation learning by behavioral cloning) while in other cases a feedback signal can determine what data is actually relevant for the system (directly in RL and somewhat more indirectly in imitation learning by inverse RL). Also, the type of data generation will determine what robot learning methods are applicable as indicated in Fig. 15.1. For example, while expert data is crucial for imitation, it may simply be the wrong data to learn from in model learning.

Data for Robot Learning

In comparison to many other machine learning domains, robot learning suffers from a variety of complex real-world data problems. Real-world training time is limited – hence, only relatively few complete executions of a task can ever be generated. These episodes are frequently perceived noisily, have a fair amount of variability in the outcome, do not cover all possible scenarios and most often do not include all reactions to external stimuli. While episodes are scarce, the samples executed during a trial are not (but are often not helpful as they contain less information for some types of learning). Instead, high-dimensional data is obtained at a fast rate (e.g., proprioceptive information at 500 Hz to 5 kHz, vision at 30–200 Hz, tactile at 50 Hz to 5 kHz depending on the measurement mode). The data the robot can learn from is usually generated by the imperfect controller that needs to be improved. Thus, generating *interesting* data that has sufficiently useful information is a recurring problem in robot learning, discussed under various names, like exploration/exploitation tradeoff, persistent excitation, etc. Last not least, for high-dimensional robot systems (like humanoids), there is no *representative training data set* to learn from. A small change in posture of a robot can radically change in which part of the workspace the robot operates. Rapidly learning on the fly is frequently more important than squeezing the most of information from a few data points. Sharing data across different robots would be desirable, envisioning a *cloud robotics* approach. However, so far, even various instantiations of the same robot model can create quite different data depending on their wear and tear, calibration, and maintenance. Sharing data across different robot models has not seen a lot of success, as kinematic and dynamic differences can lead to rather different control and planning realizations. Thus, machine learning techniques for robotics

become quickly rather specialized and domain/robotic specific.

What Feedback Is Available for Learning?

A straightforward way to categorize robot learning approaches is given by the type of feedback [15.11]. A scalar performance score such as a reward or cost will often result in a *RL* approach. A presented desired action or predicted behavior allow supervised learning approaches such as model learning or direct imitation learning. Feedback in terms of an explanation has become most prominent in inverse *RL*. These methods will be explained in more detail below. Note

that unsupervised learning problems where no feedback is required also can be found in robotics [15.5, 12].

15.1.3 Notation

In the next section and in Fig. 15.1, we will use the following notation. In general, we follow the tradition in *RL* [15.13]. When it comes to specific control problems, we use \mathbf{q} for a vector of states in configuration space (often called joint-space), \mathbf{u} for motor commands in configuration space, and \mathbf{x} for a state in task- or effector-space.

15.2 Model Learning

In recent years, methods to learn models from data have become increasingly interesting tools for robotics. There are a variety of reasons for this development. First, robot control – as needed in less structured dynamic and more stochastic environments – requires model-based control to realize high compliance, since stiff control without good models exposes the robot and its environment to more risk of damage. Second, due to the complexity of modern robot systems, standard models like rigid body dynamics are only rough approximations which do not accurately model unknown sources of nonlinearities from actuation (hydraulics and motor saturation), passive elements like wires, hydraulic hoses, cable stretch, and/or sources of friction and stiction. Finally, interaction with an unstructured, uncertain, and human-inhabited environment may require to learn models on the fly [15.14, 15]. In addition, wear and tear of a robot in continual use will create drifting models. All these issues can be addressed by

learning models directly from measured data, ideally in a continual and incremental on-line fashion, using appropriate nonlinear function approximation techniques.

We discuss different types of models (forward models, inverse models, mixed models, and operator models) in Sect. 15.2.1, along with difference architectures for model learning in Sect. 15.2.2. Some of the challenges that arise in these models in the domain of robotics are discussed in Sect. 15.2.3. How models can be learned using machine learning techniques are described in Sect. 15.2.4, and examples where model learning has proven to be helpful for the action generation in complex robot systems [15.14, 16–21] are highlighted in Sect. 15.2.5.

While this chapter attempts to give a fairly exhaustive overview on model learning in robotics, it is of course not complete due to the space constraints of a book chapter. An extended version of this section can be found in [15.9].

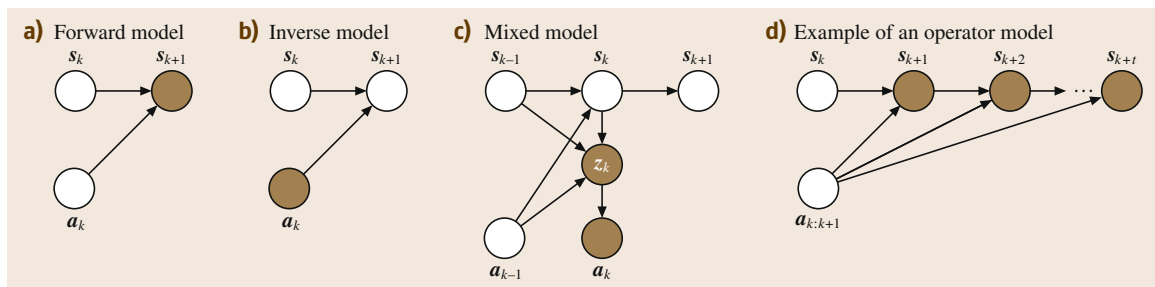

Fig. 15.2a–d Graphical models for different types of models. The *white nodes* denote the *observed* quantities, while the *brown nodes* represent the quantities to be *inferred*. (a) The forward model allows inferring the next state given current state and action. (b) The inverse model determines the action required to move the system from the current state to the next state. (c) The mixed model approach combines forward and inverse models in problems where a unique inverse does not exist. Here, the forward and inverse models are linked by a latent variable z_k . (d) The operator model is needed when dealing with finite sequences of future states

15.2.1 Model Types

Models represent the functional relationship between input and output variables. If we can observe the current state s_k of a system and the action a_k currently applied to the system, we can attempt to predict the next state s_{k+1} , which is called a forward model with mapping $(s_k, a_k) \rightarrow s_{k+1}$. We can also use the inverse model to infer the current action, i. e., the relation $(s_k, s_{k+1}) \rightarrow a_k$, if we know the current state and the desired or expected future state. There are also approaches combining forward and inverse models for prediction which we will refer to as mixed model approaches. However, for many applications the system behavior has to be predicted for the next t -steps rather than for the next single step; models that predict a series of states will be called operator models. Graphical depictions of these different models are shown in Fig. 15.2.

Forward Models

Forward models predict the next state of a dynamic system given the current action and current state. The forward model directly corresponds to the state transfer

$$s_{k+1} = f_{\text{forward}}(s_k, a_k). \quad (15.1)$$

This function expresses the causal physical properties of the system, and the learning of such causal mappings is a well-defined problem using standard regression techniques. While forward models are unique mappings in classical physics, there are several cases where forward models alone do not provide sufficient information to uniquely determine the next system's state [15.22]. For instance, when a pendulum is located at its unstable equilibrium point, it will tend to go either to the left or right rather than remain in the center. Nevertheless, the prediction of the forward model would be for the pendulum to remain centered. In this case, the state transfer function is not sufficient to capture the interesting dynamics of the system [15.22, 23]. For such cases, a probabilistic model $T(s_{k+1}, a_k, s_k) = P(s_{k+1}|s_k, a_k)$ may be more appropriate as it captures both likely modes with a conditional density instead of just the mean behavior.

An early application of forward models in classical control is the Smith predictor, where the forward model is employed to cancel out delays imposed by the feedback loop [15.24]. Subsequently, forward models have been applied in the context of model reference adaptive control (MRAC) [15.25]. MRAC is a control system in which the performance of an action is predicted using a forward reference model. The controller adjusts the action based on the resulting error between the desired and current state. Hence, the policy π for MRAC can

be written as

$$\pi(s) = \underset{a}{\operatorname{argmin}} (f_{\text{forward}}(s, a) - s_{\text{des}}), \quad (15.2)$$

where s_{des} denotes a desired trajectory and s represents the observed state. MRAC was originally developed for continuous-time system and extended later for discrete and stochastic systems [15.25]. Applications of MRAC can be widely found for robot control, such as adaptive manipulator control [15.26].

Further applications of forward models can be found in the wide class of model predictive control (MPC) [15.27]. MPC computes optimal actions by minimizing a given cost function over a certain prediction horizon N . The MPC control policy can be described by

$$\pi(s) = \underset{a:t:t+N}{\operatorname{argmin}} \sum_{k=t}^{t+N} F_{\text{cost}}(f_{\text{forward}}(s_k, a_k), s_{k,\text{des}}, a_k), \quad (15.3)$$

where $F_{\text{cost}}(s, s_{\text{des}})$ denotes the cost of an action a_k resulting in a state s away from the desired state s_{des} . MPC was first developed for linear system models and, subsequently, extended to more complex nonlinear models with constraints [15.27]. Forward models have also been essential in model-based RL approaches, which relate to the problem of optimal control [15.28–30]. Here, the forward models describe the transition dynamics determining the probability of reaching the next state given current state and action. In contrast to previous applications, the forward models incorporate a probabilistic description of the system dynamics in this case [15.31, 32]. Example applications of forward models for optimal control are given in the case studies in Sect. 15.2.5, *Simulation-Based Optimization*.

Inverse Models

Inverse models predict the action required to move the system from the current state to a desired future state. In contrast to forward models, inverse models represent an anticausal system. Thus, inverse models may not exist or be well defined. However, for several cases, such as for inverse dynamics of nonoveractuated robots, the inverse relationship is well-defined. Ill-posed inverse modeling problems can be solved by introducing additional constraints, as discussed in Sect. 15.2.1, *Mixed Models*.

For control, applications of inverse models can be traditionally found in computed torque robot control, where the inverse dynamics model predicts the required torques, i. e., the action, to move the robot along a desired joint space trajectory. Thus, the computed torque

control policy can be described by

$$\pi(s) = f_{\text{inverse}}(s, s_{\text{des}}) + k(s - s_{\text{des}}), \quad (15.4)$$

where the function $k(s - s_{\text{des}})$ is an error correction term (e.g., a proportional-derivative (PD)-controller since both positions and velocities are normally part of the state in a second order dynamical system) needed for stabilization of the robot. If an accurate inverse dynamics model is given, the predicted torques are sufficient to obtain a precise tracking performance. The inverse dynamics control approach is closely related to the computed torque control method.

Here, the feedback term acts through the inverse model of the system giving a control policy,

$$\pi(s) = f_{\text{inverse}}[s, s_{\text{des}} + k(s - s_{\text{des}})]. \quad (15.5)$$

If the inverse model perfectly describes the inverse dynamics, inverse dynamics control will perfectly compensate for all nonlinearities occurring in the system. Control approaches based on inverse models are well-known in the robotics community, and have gained increasing popularity since the late 1980s, as the increase in computational power and the existence of torque-controlled robots have allowed computing more complex models for real-time control. The concept of feedback linearization is another, more general way to derive inverse dynamics control laws, offering possibly more applications for learned models [15.33, 34].

Mixed Models

In addition to forward and inverse models, there are also methods combining both types of models. Since modeling the forward relationship is well defined while modeling the inverse relation may be an ill-posed problem, the basic idea behind the combined mixed model is that the information encoded in the forward model can help to resolve the nonuniqueness of the inverse model. A typical ill-posed inverse modeling problem is the inverse kinematics of redundant robots. Given a joint configuration q , the task space position $x = f(q)$ can be determined exactly (i.e., the forward model is well defined), while there may be many possible joint configurations q for a given task space position x , i.e., the inverse model could have infinitely many solutions and deriving an average suitable solution is not straightforward. The problem is that the set of inverse solutions may not form a convex set. Thus, when learning such inverse mappings, the learning algorithm will potentially average over the nonconvex set, giving rise to an invalid solution.

The ill-posedness of the inverse model can be resolved if it is combined with the prediction of a forward

model, which checks whether the proposed inverse solution results in the desired state [15.35]. If not, the remaining error can be used to adjust the learned inverse model such that it chooses a valid solution.

The mixed model approach, i.e., the composite of forward and inverse models, was first proposed in conjunction with the distal teacher learning approach [15.35], and discussed in Sect. 15.2.2, *Distal Teacher Learning*. The proposed mixed models approach has subsequently evoked significant interest and has been extensively studied in the field of motor control [15.36, 37]. Furthermore, the mixed model approach is supported by some evidence that the human cerebellum can be modeled using forward-inverse composite models, such as MOSAIC [15.38, 39]. While mixed models have become well known in the neuroscience community, the application of such models in robot control is not yet widespread. Pioneering work on mixed models in the control community can be found in [15.40, 41], where mixed models are used for model reference control of an unknown Markov jump system. Despite that mixed model approaches are not widely used in control, with the appearance of increasingly more humanoid robots, biologically inspired robot controllers are gaining more popularity and the ones based on mixed models may present a promising approach [15.17, 42, 43].

Operator Models

The models from the preceding sections are mainly used to predict a single future state or action. However, in many problems, such as open-loop control, one would like to have information of the system for the next t -steps in the future. This problem is the multi-step ahead prediction problem, where the task is to predict a sequence of future values without the availability of output measurements in the horizon of interest. We will term the models which are employed to solve this problem as operator models. It turns out that such operator models are difficult to develop because of the lack of measurements in the prediction horizon. A straightforward idea would be to apply single-step prediction models t times in sequence, in order to obtain a series of future predictions. However, this approach is susceptible to error accumulation, i.e., errors made in the past are propagated into future predictions. An alternative is to apply autoregressive models which are extensively investigated in time series prediction [15.44], in order to employ past predicted values to predict future outcomes.

Combining operator models with control was first motivated by the need of extension of forward models for multi-step predictions [15.45]. In more recent work, variations of traditional ARX and ARMAX models for

Table 15.1 Overview on model types associated with applicable learning architectures and example applications

Model type	Learning architecture	Example applications
Forward model	Direct modeling	Prediction, filtering, learning simulations, optimization
Inverse model	Direct modeling (if invertible), indirect modeling	Inverse dynamics control, computed torque control, feedback linearization control
Mixed model	Direct modeling (if invertible), indirect modeling, distal-teacher	Inverse kinematics, operational space control, multiple model control
Operator model	Direct modeling	Planning, optimization, model predictive control, delay compensation

nonlinear cases have been proposed for control [15.46, 47]. However, operator models based on some parametric structures, such as ARX or ARMAX, have shown to have difficulties in more complex systems. The situation is even worse in the presence of noise or complex nonlinear dynamics. These difficulties give reasons to employ nonparametric operator models for multi-step predictions [15.48, 49].

15.2.2 Model Learning Architectures

In the previous section, we have presented different prediction problems that require different types of models. A central question is how to learn and adapt these different models while they are being used. We will distinguish between direct modeling, indirect modeling, and the distal teacher approach. Table 15.1 shows an overview of model types associated with applicable learning architectures. These architectures can be observed in Fig. 15.3.

Direct Modeling

Direct learning is probably the most straightforward and most frequently applied way to obtain a model despite that it is not always applicable. In this learning paradigm, the model is directly learned by observing the inputs and outputs, creating a supervised learning problem. Direct model learning can be implemented using most regression techniques, such as linear regression, local linear regression, recursive regression [15.50, 51], neural networks [15.52, 53], or other statistical approximation techniques, currently mostly based on kernel methods [15.54, 55].

An early example for direct learning control was the self-tuning regulator that generates a forward model and adapts it online [15.56]. Assuming the estimated forward model is correct (also called the certainty equivalence principle), the self-tuning regulator will estimate an appropriate control law online. However, the forward model in the traditional self-tuning regulator has a fixed parametric structure and, hence, it cannot deal automatically with unknown nonlinearities [15.47, 57]. The main reason why parametric models need to be used in direct modeling techniques is that such model parameterization is necessary for a convenient formu-

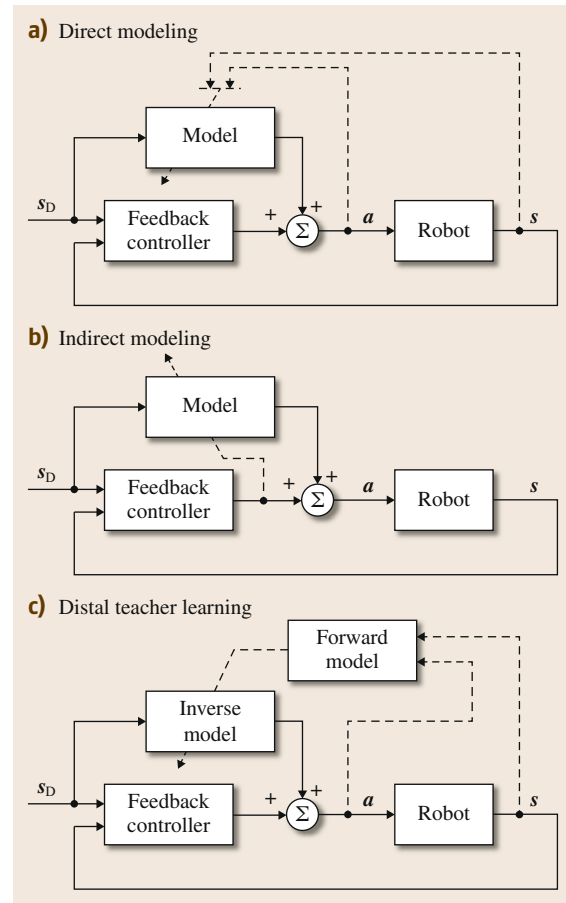

Fig.15.3a–c Learning architectures in model learning applied to control. **(a)** In the direct modeling approach, the model is learned directly from the observations – the given example shows learning and inverse model. **(b)** Indirect modeling approximates the model using the output of the feedback controller as error signal. **(c)** In the distal teacher learning approach, the inverse model’s error is determined using the forward model. The resulting models will converge to an identity transformation

lation of the control law and, more importantly, for the rigorous stability analysis. As the parametric model structure is often too limited for complex robot systems, learning methods with more degrees of freedom

are needed, such as neural networks or other machine learning techniques [15.58, 59]. However, including sophisticated learning algorithms in control makes the analysis more complex if not impossible. Some examples of nonparameteric learning for control have been applied to unmanned airplane control [15.60], where the learning system models can prevent the airplane from crashing in case of changes in the airplane dynamics, e.g., due to failure of the mechanics.

Inverse models can also be learned in a direct manner if the inverse mapping is well defined. A well-known example is the inverse dynamics model required by computed torque and inverse dynamics control [15.61, 62]. If direct modeling is applicable, learning becomes straightforward and can be achieved using standard regression techniques [15.14, 63, 64]. Early work in learning inverse models for control attempted to adapt a parametric form of the rigid body dynamics model which is linear in its parameters and, hence, can be estimated from data straightforwardly using linear regression [15.65–67]. In practice, the estimation of dynamics parameters is not always straightforward. It is hard to create sufficiently rich data sets so that physically plausible parameters can be identified [15.15], and when identified online, additional persistent excitation issues occur [15.68]. Models with fixed parametric structures are not capable of capturing certain nonlinearities; hence, more sophisticated models have been introduced for learning inverse dynamics, such as neural networks [15.64, 69] or statistical nonparametric models [15.14, 63, 70]. There have also been attempts to combine parametric rigid body dynamics model with nonparametric model learning for approximating the inverse dynamics [15.71]. Similar as in inverse dynamics models, feedback linearization can also be used in conjunction with direct model learning. Again, the nonlinear dynamics can now be approximated using neural networks or other nonparametric learning methods [15.60, 72]. Stability analysis of feedback linearization control with learned models is possible extending the cases where the nonlinear dynamics could not be canceled perfectly [15.60]. It should be noted that learning an inverse dynamics model $(s, s_{\text{des}}) \rightarrow \mathbf{a}$ can have very slow learning performance when the initially learned model is rather far from reality. In this case, the predicted action \mathbf{a} will create outcomes that are very far away from s_{des} , such that the learning system, when trying out the bad action \mathbf{a} , can hardly extract any useful information from this experience how to actually realize s_{des} .

While direct learning is mostly associated with learning a single type of model, it can also be applied to mixed models and operator models. The mixed model approach (e.g., combining inverse and forward models)

finds its application in learning control for multiple-module systems. The basic idea is to decompose a complex system into many simpler subsystems which can be controlled individually [15.41]. The problem is how to choose an appropriate architecture for the multiple controllers, and how to switch between the multiple modules. Following the multiple-module idea, each controller module consists of a pair of inverse and forward models in the mixed model approach. The controller can be considered as an inverse model, while the forward model is essentially used to switch between the different modules [15.36]. Such multiple pairs of forward and inverse models can be learned directly using gradient-descent methods or expectation-maximization [15.42]. Direct learning of operator models has been done with neural networks [15.73]. In more recent work, probabilistic methods are employed to learn such operator models [15.48, 49].

Indirect Modeling

Direct learning works well when the functional relationship is well defined. However, there can be situations where the inverse relationship is not well defined, such as in the differential inverse kinematics problem. In such cases, inverse models can often still be learned, but in an indirect way. One such indirect modeling technique is feedback error model learning [15.74]. Feedback error learning relies on the output of a feedback controller that is used to generate the error signals employed to learn the feedforward controller. In problems, such as feedforward inverse dynamics control [15.61], this approach can be understood particularly well: if the inverse dynamics model is perfect, the feedback controller is not needed and its output will be zero. If it is nonzero, it corresponds to the error of the feedforward model [15.61]. The intuition behind feedback error learning is that by minimizing the feedback errors for learning the inverse model, the feedback control term will be decreasing as the model converges.

Compared to the direct model learning, feedback error learning is a goal-directed model learning approach resulting from the minimization of feedback error – in this error can only be zero if the goal was achieved. Another important difference between feedback error learning and direct learning is that feedback error learning has to perform online, while direct model learning can be done both online and offline. Additionally, feedback error learning does not create supervised learning data in the classical sense: the feedback error is not computed from an output target, but just from an error that represents the gradient toward better performance. This issue, and additionally a complex interaction between PD gains and learning stability [15.75] can make

it more complex to set up a successful feedback error learning system.

Feedback error learning is biologically motivated due to its inspiration from cerebellar motor control [15.37]. It has been further developed for control with robotics applications, originally employing neural networks [15.76, 77]. Feedback error learning can also be used with various nonparametric learning methods [15.75]. Conditions for the stability of feedback error learning control in combination with nonparametric approaches have also been investigated [15.75].

Indirect model learning can also be used in the mixed model approach [15.78]. Here, the attempt has been made to combine the feedback error learning with the mixture of experts' architecture to learn multiple inverse models for different manipulated objects, where the inverse models are learned indirectly using the feedback error learning approach [15.78]. The forward model is used for training a gating network, as it is well defined. The gating network subsequently generates a weighted prediction of the multiple inverse models, where the predictors determine the locally responsible models.

Distal Teacher Learning

The distal teacher learning approach was motivated by the necessity to learn general inverse models which suffer from the ill-posedness problem [15.35]. Here, the nonuniqueness of the inverse model is resolved by the distal teacher which determines the error of the inverse model using a forward model. Unlike the feedback error learning approach, this insight allows directly aiming at a globally consistent inverse model instead of local on-policy optimization. The distal teacher employs two interacting learning process: one process where the forward model is learned, and the other process where the learned forward model is used for determining the error of the inverse model. In the original distal learning approach, the inverse model's output is validated by the forward model, as the composite of these models yields an identity mapping if perfectly learned [15.35]. The intuition behind this approach is that the inverse model will learn a correct solution by minimizing the error between the output of the forward model and the input to

the inverse model. Thus, the inverse model will result in solutions that are consistent with the forward model. The distal teacher approach has successfully learned particular solutions for multi-valued mappings, such as inverse kinematics of redundant robots [15.35]. Similar to feedback error model learning [15.74], distal teacher learning is also a goal-directed learning method applicable for various robot control scenarios.

The distal learning approach is particularly suitable for control when combining with the mixed models, as it naturally incorporates the mixed model principle. The distal teacher learning approach with mixed models has motivated a number of follow-up projects with several robot control applications [15.17, 43, 79].

15.2.3 Model Learning Challenges and Constraints

Given different types of models and their associated learning architectures, it may not be straightforward to apply machine learning methods [15.54, 55, 80] to these models in robotics. Several important problems arise that need to be addressed before learning methods can be successfully applied, and are summarized in Table 15.2.

Data Challenge

In order to learn a *good* model for applications in robotics, the sampled data has to cover a preferably large region of the model state space, and ideally cover it densely. Of course, in high-dimensional systems, one can never cover the complete state space – indeed, in complex robots like humanoids with state spaces of over 30 dimensions, only a very tiny fraction of the possible space can be explored in a lifetime. Thus, one can only hope to sample data in a task specific way, which is usually just in a very small part of the entire data space. For the purpose of generalization and accuracy, the data has to be sufficiently rich, i. e., it should contain as much information about the system as possible. Thus, generating large and rich data sets for model learning is an essential step. This step often requires additional excitation of the robot system during data generation, analogous to persistent excitation in classical system identification [15.68].

Table 15.2 Some challenges for model learning in robotics

Data challenges	Algorithmic constraints	Real-world challenges
High-dimensionality	Incremental updates	Safety
Smoothness	Real-time	Robustness
Richness of data	Online learning	Generalization
Noise	Efficiency	Interaction
Outliers	Large data sets	Stability
Redundant data	Prior knowledge	Uncertainty
Missing data	Sparse data	In the environment

Many machine learning methods for regression assume that the model to be learned is sufficiently smooth. However, there are many applications in robotics where the approximated functions are known to be nonsmooth – one example is a stiction-friction model. Such nonsmooth functions are sometimes approximated using kernel methods, where special kernels need to be defined in order to take the expected nonsmoothness in account [15.54, 55]. Discontinuities in a function can also be approximated by learning how to switch discontinuously between local models [15.81].

Difficulties arising from the large number of degrees of freedom in robotics can also be mitigated using dimensionality reduction methods [15.82, 83]. Dimensionality reduction is based on the insight that the useful information in the data may be represented by a low-dimensional manifold of the original input space. Dimensionality reduction methods have proven to be a powerful method for model learning in high-dimensional robot systems [15.63, 84].

As the data is sampled over a possibly long period of time in many robotics applications [15.85], problems of redundant and irrelevant data can occur. Redundant and irrelevant data can bias the model which severely degenerates the generalization performance. To overcome these issues, data needs to be filtered that is informative for the learning process [15.70, 86]. Dealing with noise and outliers is always a challenging problem for robot learning. Recent work in the machine learning community has addressed this problem by developing regularization frameworks based on statistical learning theory. The basic idea is to constrain the model to be learned in order to alleviate the contributions made by the noisy components in the data. Examples of regularized model learning methods include support vector regression and Gaussian process regression [15.87, 88]. Methods that explicitly account for noise in the data can significantly improve their generalization performance.

Algorithmic Constraints

In many scenarios, robot learning algorithms have to deal with massive amounts of data coming from their sensors. Thus, algorithms need to be efficient in terms of computation without sacrificing learning accuracy [15.89]. Fast and real-time computation presents a challenging problem. Standard model learning approaches, such as Gaussian process regression, for example, scale cubically in the number of training data points, preventing a straightforward usage in robotics. Sparse and reduced set methods smartly reduce the size of training data and, thus, decrease the computational effort for the learning and the prediction step [15.90]. Efficient implementations using parallel computation

may also be used to speed up machine learning algorithms [15.91].

Online learning is also needed for continuous adaptation to a changing world which is essential to make robots more autonomous [15.85]. Most machine learning methods are developed for learning in batch mode, while online learning requires incremental approximation of the model [15.14, 92]. An advantage of online model learning is the ability to uncover interesting state-space regions during task execution.

For some robots, it may be difficult or expensive to obtain a lot of data for learning. In these cases, we need algorithms which allow us to incorporate additional prior knowledge to improve the learning performance in the presence of sparse data [15.93, 94]. In kernel methods, prior knowledge can be specified by feature vectors which can be used to define appropriate kernels [15.93]. In contrast, probabilistic frameworks allow specifying a priori information [15.54]. Furthermore, prior knowledge, if given as a parametric model, can be inserted into nonparametric models yielding semiparametric learning approaches [15.71, 95]. Semiparametric models have shown to be capable in learning competitive models, when little data is available [15.71].

Real-World Constraints

Ensuring safe interaction of robots with human beings in everyday life, machine learning algorithms developed for robotics applications have to minimize the risk of injury and damage. For critical applications, such as medical or service robotics, robustness and reliability are among the most important criteria which have to be fulfilled by model learning. Learning becomes more robust by employing feature selection as a preprocessing step, and has been used in several robotics application in vision and control [15.70, 96].

Robustness also requires the ability of the learning algorithm to deal with missing data. Missing data due to measurement errors poses a difficult problem for model learning in robotics. Recently, probabilistic learning methods have been used to infer the missing components in the training data [15.97]. An advantage of probabilistic methods comes from the ability to assign uncertainty to the predicted values, making it easier to deal with missing and imprecise data.

15.2.4 Model Learning Methods

We consider model learning in the context of supervised learning, where the inputs \mathbf{x} and outputs \mathbf{y} are given. The true output data is corrupted by noise ϵ , i. e.,

$$\mathbf{y} = f(\mathbf{x}) + \epsilon. \quad (15.6)$$

Table 15.3 A large variety of machine learning methods have been applied in model learning for robotics. We distinguish between global and local methods, as well as semilocal methods which combine both approaches. The methods differ in the training mode and their online capabilities. For computational complexity, n denotes the total number of training points, m is the number of data points in a local model, and M is the number to local models

Method	Type	Mode	Online	Complexity	Learning applications
Locally weighted projection regression [15.80]	Local	Incremental	Yes	$\mathcal{O}(n)$	Inverse dynamics [15.63], Foothold quality model [15.21]
Local Gaussian process regression [15.14]	Local	Incremental	Yes	$\mathcal{O}(m^2)$	Inverse dynamics [15.14]
Gaussian mixture model [15.98]	Semilocal	Batch	No	$\mathcal{O}(Mn)$	Human motion model [15.99]
Bayesian committee machine [15.100]	Semilocal	Batch	No	$\mathcal{O}(m^2n)$	Inverse dynamics [15.54]
Sparse Gaussian process regression [15.101]	Global	Incremental	Yes	$\mathcal{O}(n^2)$	Transition dynamics [15.32], Task model [15.102]
Gaussian process regression [15.103]	Global	Batch	No	$\mathcal{O}(n^3)$	Terrain model [15.104], State estimation model [15.105]
Support vector regression [15.55]	Global	Batch	No	$\mathcal{O}(n^2)$	ZMP control model [15.106], Grasp stability model [15.107]
Incremental support vector machine [15.108]	Global	Incremental	Yes	$\mathcal{O}(n^2)$	Inverse dynamics [15.109]

Note that the noise is additive to $f(\mathbf{x})$; models that address noise in the inputs can be developed as well [15.110]. The performance of a model is given by its *generalization* ability, i. e., the learned model should be able to provide precise predictions of the output on new input data. Different learning techniques make different assumptions on how to model the function f given the data. From a function approximation point of view, we will distinguish between *global* and *local* techniques. Beyond the local and global types of model learning, there are also approaches that combine both ideas. An example of such a hybrid approach is the mixtures of experts [15.98, 111]. Here, the data is partitioned into smaller local models by a learned gating network, and prediction is accomplished by fusing local model predictions. Mixture of experts have been further embedded into a Bayesian learning framework, giving rise to a number of Bayesian hybrid approaches such as committee machines [15.100], mixtures of Gaussian models [15.112], or infinite mixtures of experts [15.113].

Global Regression

Global regression techniques model the underlying function f using *all* observed data [15.114], i. e., every data point is potentially adjusting every parameter of the learning system. A straightforward way to model the function f is to assume a parametric structure, such as linear or polynomial models or multilayer perceptron neural networks, and to fit the model parameters using training data [15.52, 114, 115]. However, fixing the model with a parametric structure beforehand may not suffice to explain the sampled data with sufficient accuracy, which motivates nonparametric model learning frameworks [15.54, 55, 115]. Nonparametric learning

does not mean that there are no parameters, just that the correct number of relevant parameters is unknown, and that it is unlikely that a finite set of parameters would suffice to model the entire regression problem.

In the last two decades, parametric and nonparametric regression methods have been focussing on functions f modeled as

$$f(\mathbf{x}) = \boldsymbol{\theta}^T \boldsymbol{\phi}(\mathbf{x}), \quad (15.7)$$

where $\boldsymbol{\theta}$ is a weight vector and $\boldsymbol{\phi}$ is a vector of nonlinear functions, also called *features* or *basis-functions*. $\boldsymbol{\phi}$ projects \mathbf{x} into some high-dimensional space, in which the learning problem is assumed to become linear in the parameters. The basic idea behind nonparametric regression is that the optimal model structure should be obtained from the training data. Hence, the size of the weight vector $\boldsymbol{\theta}$ is not fixed but can increase with the number of training data points. In contrast to nonparametric statistical approaches, other popular function approximation methods, such as neural networks, fix the model structure beforehand [15.52], like the number of nodes and their connections. However, there is a connection between artificial neural networks and probabilistic approaches [15.116, 117] using the formalization in (15.7).

Learning systems as formalized in (15.7) are mostly discussed as kernel methods [15.55]. Learning a model is equivalent to finding a tradeoff between the model's complexity and the best fit of the model to the observed data. Thus, it is desirable to have a model which is simple but at the same time can explain the data well. The number of features (i. e., the length of feature vector $\boldsymbol{\phi}$) has a direct correlation with the complexity of the regression model, as the more features one allows, usually the more powerful the learning system

becomes, but it also takes more data to constrain the open parameters of the model. One of the key insights of kernel methods [15.54, 55] was that one can actually work with *infinitely* many features using the so-called *kernel trick*, where the formulation of the regression problem only involves inner products of the feature vectors $\phi(x_i)^T \phi(x_j)$ of any two inputs x_i and x_j , and that this inner product can often be computed in closed form by a kernel function $k(x_i, x_j)$. This approach introduces a dual form of the regression learning problem where the number of open parameters is identical to the number of n training data, and not the number of features. In support vector regression (SVR) [15.55], a sparsification process will choose the minimal number of parameters needed to represent the training data. In Gaussian process regression [15.54], a probabilistic approach is taken that places a prior distribution over θ . The posterior parameters can subsequently be obtained by optimizing the corresponding marginal likelihood.

Kernel and probabilistic methods have proven to be successful tools for model learning over the last decade, resulting in a number of widely applied regression methods [15.87, 88, 118]. These methods can be applied to high-dimensional data. They can also deal well with noisy data, as the noise is taken in account indirectly by regularizing the model complexity. Furthermore, they are relatively easy to use, as several black-box implementations are available. However, the major drawback of these methods are the computational complexity. For instance, for Gaussian process regression the complexity scales cubically in terms of the number of training data points. Thus, one active research line in machine learning is to reduce the computational cost of those approaches. Due to customized techniques for robotics, kernel and probabilistic regression techniques found their ways into several robotics applications, such as robot control [15.70], sensor modeling [15.119], or state estimation [15.105].

Local Learning Methods

The basic idea of local regression techniques is to estimate the underlying function f within a *local neighborhood* around a query input point x_q . The data points in this neighborhood can then be used to predict the outcome for the query point. Generally, local regression models can be obtained by minimizing the following cost function J using n training data points

$$J = \sum_{k=1}^n w [(x_k - x_q)^T D (x_k - x_q)] \|y_k - \hat{f}(x_k)\|^2. \quad (15.8)$$

As indicated by (15.8), the essential ingredients for a local regression model are the neighborhood function w

and the local model \hat{f} . The neighborhood function w , which is controlled by a distance metric D , often simplified as a scalar width parameter $D = 1/hI$, measures the distance between a query point x_q to the points in the training data. The local model \hat{f} describes the function structure used to approximate f within the neighborhood around x_q [15.120, 121]. Depending on the complexity of the data, different function structures can be assumed for the local model \hat{f} , such as a linear or a polynomial model. The open-parameters of \hat{f} can be estimated straightforwardly by minimizing J with respect to these parameters.

The choice of the neighborhood function and its distance metric parameter is more involved. Several techniques have been suggested for estimating D for a given w , including the minimization of the leave-one-out cross-validation error and adaptive bandwidth selection [15.122, 123].

Due to their simplicity and computational efficiency, local regression techniques have become widespread in model learning for robotics [15.124–126]. In the last decade, novel local regression approaches were further developed in order to cope with the demands in real-time robotics applications, such as locally weighted projection regression [15.92, 127]. Inspired by local regression techniques, these methods first employ a partitioning of the input space into smaller local regions, for which locally linear models are approximated. A useful metaphor is to imagine that the input space is partitioned into disjoint boxes, and for the data points falling into each of these boxes, an independent local model is fit, usually of very simple complexity, like locally linear models.

In addition to the computational efficiency, local methods can deal with less smooth functions and do not require the same smoothness and regularity conditions as global regression methods. However, it has been shown in practice that local methods suffer from problems induced by high-dimensional data, as notions of locality break down for sparse, high-dimensional data. Furthermore, the learning performance of local methods may be sensitive to noise and heavily depends on the way how the input space is partitioned, i.e., the configuration of the neighborhood function w . These problems still present an active research topic [15.17, 128].

Several attempts have been made to scale local regression models to higher dimensional problems as required for many modern robotics systems. For example, locally weighted projection regression combines local regression with dimensionality reduction by projecting the input data into a lower dimensional space, where local regression is employed afterward [15.92]. Other methods combine nonparametric

probabilistic regression, such as Gaussian process regression, with the local approaches while exploiting the strength of probabilistic methods for model learning in high-dimension [15.14, 17]. Local learning methods are very well suited to parallelization on modern computer hardware, as each local model can be fit independently.

15.2.5 Applications of Model Learning

Several representative examples of model learning are illustrated in the following sections.

Simulation-Based Optimization

As forward models directly describe the causal dynamic behavior of a system, learning such models has received much attention in model-based control, particularly for optimal control problems. In optimal control, a forward model is needed to predict the behavior of the control system over an extended time horizon in order to optimize the control policy. If an analytical model is inaccurate, learning the model offers an interesting alternative.

Atkeson and Morimoto [15.29] have been among the first to explore this approach using differential dynamic programming [15.129] for optimizing open-loop control policies. The basic idea was to use receptive field-weighted regression (a type of locally weighted regression) to learn the models of the cost function and the state transition. Differential dynamic programming locally linearizes the state transition model and generates a local quadratic approximation of the cost. These approximations are used to improve an open-loop policy where the linearizations are also updated after every policy update [15.29]. Atkeson and Morimoto used the method to learn the underactuated pendulum swing up task, where a pole is attached to with a passive joint to the endeffector of a robot arm. The goal of the robot is to bring the pole from a hanging to an upright position. Hence, the system needs to *pump* energy into the pendulum in order to swing it up (Fig. 15.4a). Subsequently, the pole needs to be stabilized at the upright position [15.130]. Starting from an unconstrained human demonstration, the robot was able to successfully learn the swing up and balance task after three trials [15.130]. The local trajectory optimization technique has been further extended to biped robot walking [15.131]. More recently, a related approach with parametric function approximation has been applied by Abbeel et al. [15.132] to learn autonomous helicopter flight (VIDEO 353).

While Atkeson and Morimoto [15.29] and Abbeel et al. [15.132] used the forward model as an implicit simulator, Ng et al. [15.30] used it as an explicit sim-

ulator (as originally suggested by Sutton [15.28] in form of the DYNA model). Here, with the help of the forward model, complete trajectories (or roll-outs) were simulated. The predictions of the forward model were perturbed by Gaussian noise with a repeating, fixed noise history. This injection of noise requires the learned controller to be robust to noise and modeling errors, while the re-use of the noise history reduces the variance of policy updates and results in much faster learning [15.133, 134]. In this way, roll-outs from a similar set of start-states are generated. The resulting performance of different control policy can be compared, which allows policy updates both by pairwise comparison or by gradient-based optimization. The approach has been able to successfully stabilize an helicopter in an inverted flight (Fig. 15.4b and VIDEO 352). A few similar examples in model predictive control (Sect. 15.2.1) exist, which employ a variety of different learning approaches such as statistical learning methods [15.48], neural networks [15.135], both for robot navigation [15.136] and helicopter control [15.137].

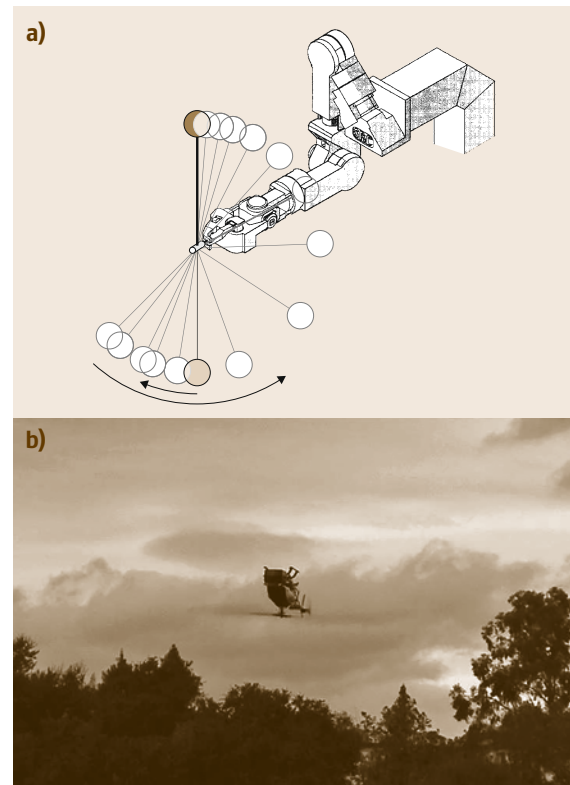

Fig. 15.4 (a) Sketch of learning a pendulum swing up task, and (b) inverse helicopter flight (courtesy of Andrew Y. Ng). In both the cases, the forward model is used to learn the dynamics of the system for policy optimization

Approximation-Based Inverse Dynamics Control

Inverse models, such as inverse dynamics models, are frequently used in robotics for feedforward control [15.62]. Inverse dynamics models characterize the required joint torques $\tau = f(q, \dot{q}, \ddot{q})$ to achieve a desired robot acceleration \ddot{q} for the state q, \dot{q} , i.e., the vectors of joint positions and velocities. In classical robot control, analytical dynamics models are derived in the framework of rigid body dynamics

$$\tau(q, \dot{q}, \ddot{q}) = \mathbf{M}(q) \ddot{q} + \mathbf{F}(q, \dot{q}), \quad (15.9)$$

where $\mathbf{M}(q)$ is the generalized inertia matrix of the robot, $\mathbf{F}(q, \dot{q})$ is a vector defined by forces/torques from Coriolis effects, centripetal effects, and gravity. This model relies on many assumptions, such as rigidity of the robot's links, negligible nonlinearities from other sources (e.g., actuators), second-order dynamics, etc. [15.62]. However, modern robotics systems with highly nonlinear components, such as hydraulic tubes or elastic cable drives, can no longer be accurately modeled with rigid body dynamics. An inaccurate dynamics model can lead to severe losses in control performance and, in the worst case, instability. Instead of modeling the inverse dynamics manually based on physics and human insight, an inverse dynamics model can be learned from sampled data. Such a data-driven ap-

proach has the advantage that all nonlinearities encoded in the data will be approximated by the model [15.14].

In most robots, the inverse dynamics model is a unique mapping from joint space into torque space, and learning inverse dynamics models is a standard regression problem. In order to generalize the learned models for a larger state space and to adapt the models for time-dependent changes in the dynamics, real-time online learning becomes necessary. However, online learning poses difficult challenges for any regression method. These problems have been addressed by real-time learning methods such as locally weighted projection regression [15.80]. *Nguyen-Tuong* and *Peters* [15.14, 70] combined the basic ideas behind the locally weighted projection regression method with Gaussian process regression [15.54], attempting to get as close as possible to the speed of local learning while having a comparable accuracy to Gaussian process regression. The resulting method has shown to be capable of real-time online learning of the robot's inverse dynamics. Instead of using local models, data sparsification methods can be employed to speed up kernel regression approaches for real-time scenarios [15.70].

It is worth noting that inverse dynamics model learning approaches can also be motivated from a biological point of view. *Kawato* [15.37] suggested that the cerebellum may act as an inverse dynamics model. Motivated by this insight, *Shibata* and *Schaal* [15.76] proposed a biologically inspired vestibulo-oculomotor control approach based on feedback-error learning of the inverse dynamics model. The problem is to stabilize the gaze of an oculomotor system that is mounted on a moving body, which creates permanent perturbations to eye (or camera) system. The cerebellum is known to predict the forces required to keep the image stabilized on the retina, based on efferent motor signals and inputs from the vestibular system. *Vijayakumar* and *Schaal* employ the locally weighted projection regression approach to learn the inverse model of the eye dynamics online [15.80]. The same locally weighted projection regression technique has also been used to learn a complete inverse dynamics model for a humanoid robot [15.63] (Fig. 15.5).

Learning Operational Space Control

Operational space control (OSC) allows a robot to accomplish a task space controller, e.g., for following a desired trajectory in task space or for impedance control [15.15, 138]. The relationship between the task space and joint space of the robot is well defined by the classical forward kinematics models $x = f(q)$, where q denotes a joint space configuration and x represents the corresponding task space position. The task space velocity and acceleration are given by $\dot{x} = \mathbf{J}(q)\dot{q}$ and $\ddot{x} =$

Fig. 15.5 The 7 degree of freedom anthropomorphic SAR-COS arm used in learning inverse dynamics, inverse kinematics, and operational space control

$\dot{\mathbf{J}}(\mathbf{q})\dot{\mathbf{q}} + \mathbf{J}(\mathbf{q})\ddot{\mathbf{q}}$, respectively, where $\mathbf{J}(\mathbf{q}) = \partial f / \partial \mathbf{q}$ is the Jacobian. To obtain the joint torques required for task space control, the dynamics model (as given in (15.9)) is needed. The direct combination of dynamics and kinematics model yields one possible operational space control law

$$\mathbf{a} = \mathbf{M}\mathbf{J}_w^+(\ddot{\mathbf{x}} - \dot{\mathbf{J}}\dot{\mathbf{q}}) + \mathbf{F}, \quad (15.10)$$

where \mathbf{J}_w^+ denotes the weighted pseudoinverse of \mathbf{J} [15.139] and \mathbf{a} represents the desired joint torques. Equation (15.10) can be employed to generate the joint torques necessary for tracking a task space trajectory determined by a reference task-space acceleration [15.15]. Note that in practical applications, such control laws often require further terms, such as a null-space control law for joint-space stabilization [15.15].

As discussed before, dynamics models can be hard to obtain and, thus, learning can be a promising alternative. Learning an operational space control law corresponds to learning an inverse model such as $(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{x}}) \rightarrow \mathbf{a}$ [15.43]. However, learning such OSC models is an ill-posed problem, as there are infinitely many possible inverse models, due to the redundancy of joint space to task space mappings. For example, infinitely many solutions for a redundant robot can be derived analytically by varying the metric W of the weighted pseudoinverse in (15.10). As the space of possible solutions is not convex (Sect. 15.2.1, *Mixed Models*), such OSC models cannot be straightforwardly learned using regression models (unless the system has no redundant degrees of freedom). Similar problems appear in the limited case of differential inverse kinematics.

Both D'Souza et al. [15.79] and Peters and Schaal [15.43] noticed that local linearizations of the mapping in (15.10) will always form a locally convex space. Hence, data sets generated by such systems will also be locally convex. They furthermore realized that the predictive abilities of forward models allows determining local regions, where a locally consistent inverse model can be learned. However, depending on how the learning data was collected, i.e., the local data distribution, learning may result in rather different solutions to the local inverse model. Thus, two neighboring local inverse models may have quite different policies how to resolve redundancy, resulting in a discontinuous jump when transitioning from one local model to the next during control. As a result, a globally consistent solution to OSC can no longer be ensured. This insight leads to two significantly different approaches. D'Souza et al. [15.79] created a differential inverse kinematics learning system (i.e., a limited special case of an operational space control law) and chose to bias the learning system by selectively generating data. However, such

an approach will generically be limited by the tradeoff between this intentional bias and the inverse model's accuracy. Peters and Schaal [15.43] treated learning of complete operational space control laws. They realized that a re-weighting of the data using an additional reward function allows regularizing these inverse models toward a globally consistent solution. Inspired by a result in analytical OSC [15.139], they suggest appropriate reward functions both for learning full OSC and differential inverse kinematics. The resulting mapping was shown to work on several robot systems. Ting et al. [15.17] presented an implementation of Peters and Schaal [15.43] approach with modern Bayesian machine learning, which sped up the performance significantly.

Instead of learning a direct OSC control law as done by Peters and Schaal [15.43], Salaun et al. [15.140] attempted to learn the well-defined differential forward kinematics as a first step (i.e., learning the Jacobian) using locally weighted projection regression. The corresponding weighted pseudoinverse of the Jacobian is subsequently computed using singular value decomposition (SVD). The obtained differential inverse kinematics model is combined with an inverse dynamics model to generate the joint space control torques [15.140]. Approximating inverse kinematics models has also been investigated in neural network learning and reservoir computing architectures [15.35, 141].

15.2.6 Future Directions

A key question in robotics is how to deal with uncertainty in the environment. As probabilistic machine learning techniques (e.g., Bayesian inference) have reached a high level of maturity [15.54], it has become clear how beneficial Bayesian machine learning can be for robot learning, especially, for model learning in the presence of uncertainty. However, machine learning techniques based on Bayesian inference are known to suffer from high computational complexity. Thus, special approximations will be needed as illustrated by the problems discussed in Sect. 15.2.3. Recently developed approximate inference methods such as in [15.90, 142] may become interesting new tools for robotics.

In order for robots to enter everyday life, they need to continuously learn and adapt to new tasks. Recent research on learning robot control has predominantly focused on learning single tasks that were studied in isolation. However, there is an opportunity to transfer knowledge between tasks, which is known as transfer learning in the field of machine learning [15.143]. To achieve this goal, robots need to learn the invariants of the individual tasks and environments and, sub-

sequently, exploit them when learning new tasks. In this context, similarities between tasks also need to be investigated and how they can be exploited for generalization [15.144].

In most of the model learning approaches, supervised learning methods are used. However, for many robot applications, target outputs are not always available. In these scenarios, semisupervised learning techniques can be useful to learn such models [15.145]. Semisupervised learning employs labeled as well as unlabeled data for model learning and can help to overcome the sparse labeling problem. It would also be beneficial to develop online versions of semisupervised approaches for real-time adaptation and learning.

Approximation-based control often still suffers from a lack of proper analysis of stability and convergence properties. Modern statistical learning the-

ory might offer new tools to derive appropriate error bounds [15.55]. For example, generalization bounds can be used to estimate the learning performance of the controller and, from this insight, further statements and conditions about stability could be made.

Learning nonunique and ill-posed mappings is a key problem for several robot applications. This problem can be considered as a nonunique labeling problem, and statistical machine learning techniques, such as conditional random fields [15.146], may help to solve the problem. A conditional model specifies the probabilities of possible target outputs given an input observation sequence. As the target outputs are conditioned on the current input observations, nonuniqueness in the mappings can be resolved. It would be beneficial to investigate how such models could be incorporated into learning control and hierarchical control frameworks.

15.3 Reinforcement Learning

Probably the most general frameworks for learning control is **RL** which enables a robot to autonomously discover optimal behaviors through trial and error interactions with its environment. No explicit teaching signal is provided, as in supervised learning, but rather learning is based on a scalar objective function that measures the overall performance of the robot.

Consider the example of training a robot to return a table tennis ball ([15.147],  VIDEO 354). In this case, the robot makes observations of dynamic variables specifying ball position and velocity as well as its internal dynamics including joint positions and velocities. These measurements capture the relevant *state* s of the system. The *actions* a available to the robot are the torque commands sent to the motors. A function π that computes the motor commands (i.e., the actions) based on the current state is the *policy*. The **RL** problem is to find a policy that optimizes the long term sum of *rewards* $R(s, a)$, as already indicated in Sect. 15.1.3. The reward function in this example could be based on the number of successful hits, or on secondary criteria like energy consumption; **RL** algorithms aim to find (near-)optimal policies that maximize the reward function over a chosen time horizon. An extended discussion of robot **RL** techniques, on which this chapter is based, can be found in [15.10].

15.3.1 Relation to Classical Control

RL is closely related to the theory of classical optimal control, as well as dynamic programming, stochastic programming, simulation optimization, stochastic

search, and optimal stopping [15.152]. Both **RL** and optimal control address the problem of finding an optimal policy (often also called the *controller* or *control policy*) that optimizes an objective function over a time horizon, and both rely on the notion of a system being described by an underlying set of states, controls and a plant or model that describes transitions between states. However, optimal control assumes perfect knowledge of the system's description in the form of a model (e.g., a model as in Sect. 15.2 that describes what the next state of the robot will be given the current state and action). For such models, optimal control ensures strong guarantees which, nevertheless, often break down due to model and computational approximations.

In contrast, **RL** operates directly on measured data and rewards from interaction with the environment. Reinforcement learning research has placed great focus on addressing cases which are analytically intractable by using approximations and data-driven techniques. An important class of approaches to **RL** within robotics centers on the use of classical optimal control techniques (e.g., linear-quadratic regulation and differential dynamic programming) to system models learned via repeated interaction with the environment [15.150, 153, 154]. A concise discussion of viewing **RL** as *adaptive optimal control* is presented in [15.155]. This path is indicated in Fig. 15.1 as *optimal control with learnt models*.

Reinforcement learning applied to robotics (Fig. 15.6) differs considerably from most well-studied **RL** benchmark problems. Problems in robotics are

Fig.15.6a–d A small sample of robots with behaviors that were reinforcement learned. These cover the whole range of aerial vehicles, robotic arms, autonomous vehicles, and humanoid robots. **(a)** The OBELIX robot is a wheeled mobile robot that learned to push boxes (after [15.148]) with a value function-based approach (courtesy of Sridhar Mahadevan). **(b)** A Zebra Zero robot arm learned a peg-in-hole insertion task (after [15.149]) with a model-free policy gradient approach (courtesy of Rod Grupen). **(c)** Carnegie Mellon’s autonomous helicopter leveraged a model-based policy search approach to learn a robust flight controller (after [15.150]). **(d)** The Sarcos humanoid DB learned a pole-balancing task (after [15.151]) using forward models

often involve high-dimensional, continuous states and actions (note that the 10–30-dimensional continuous actions common in robot RL are considered large [15.152]). In robotics, it is often unrealistic to assume that the true state is completely observable and noise free. The learning system will not be able to know precisely in which state it is and even vastly different states might look very similar. Thus, RL in robotics is often modeled as partially observed, a point we take up in detail in our formal model description below. The learning system must hence use filters to estimate the true state. It is often essential to maintain the information state of the environment that not only contains the raw observations but also a notion of uncertainty on its estimates (e.g., both the mean and the variance of a Kalman filter tracking the ball in the robot table tennis example).

Experience on a real physical system is tedious to obtain, expensive, and often hard to reproduce. Even getting to the same initial state is impossible for the robot table tennis system. Every single trial run, often called a roll-out or episode, is costly and, as a result, such applications force us to focus on difficulties that do not arise as frequently as in classical RL benchmark examples that are mostly simulation studies. In order to learn within a reasonable time frame, suitable approximations of state, policy, value function, and/or system dynamics need to be introduced. However, while real-world experience is costly, it usually cannot be replaced by learning in simulations alone. In analytical or learned models of the system, even small modeling errors can accumulate to a substantially different behavior. Hence, algorithms need to be robust with respect to models that do not capture all the details of the real system, also referred to as *under-modeling*, and to model uncertainty. Another challenge commonly faced in robot RL is the generation of appropriate reward functions. Rewards that guide the learning

system quickly to success are needed to cope with the cost of real-world experience. This problem is called *reward shaping* [15.156] and represents a substantial manual contribution. Specifying good reward functions in robotics requires a fair amount of domain knowledge and may often be hard in practice.

Not every RL method is equally suitable for the robotics domain. In fact, many of the methods thus far demonstrated on difficult problems have been model-based [15.50, 132, 157] and robot learning systems often employ policy search methods rather than value function-based approaches [15.149, 150, 158–164]. Such design choices stand in contrast to possibly the bulk of the early research in the machine learning community [15.13, 165].

15.3.2 Reinforcement Learning Methods

In RL, an agent tries to optimize the accumulated reward over a time horizon, e.g., a manipulation task or even its entire lifetime. In an *episodic* setting, where the task is restarted at the end of each episode, the objective is to maximize the total reward per episode. If the task is on-going, a discounted accumulated reward which weighs earlier rewards with less influence is typically optimized. The agent is modeled as being in an environment with state $s \in S$ and can perform actions $a \in A$. The states and actions can be either discrete or continuous and are normally multi-dimensional. A state s contains all relevant information about the agent and environment needed to model future states or observables. An action a is used to control the time evolution of the system. For example, in a navigation task, the state could be the position and orientation of the robot, whereas the action corresponds to the torques applied to the wheels.

At every time step, the agent gets a reward R , a scalar value which typically depends on its state and

action. For instance, in a navigation task, rewards could be given for reaching the target, and penalties (negative reward) would arise for expending energy. The goal of **RL** is to find a policy π that chooses action \mathbf{a} in s such as to maximize the cumulative reward over time. The policy π can be either deterministic, which always chooses the same action for each state $\mathbf{a} = \pi(s)$, or probabilistic which draws a sample action from a distribution: $\mathbf{a} \sim \pi(s, \mathbf{a}) = P(\mathbf{a}|s)$. Reinforcement learning algorithms need to discover the relations between states, actions, and rewards. Hence exploration is required to sufficiently sample these functional relationships, which can be directly embedded in the policy or performed separately as part of the learning process.

Classical **RL** approaches are based upon the assumption of a *Markov decision process* or **MDP** which models the dynamics of the environment through transition probabilities T . Given the current state s and action \mathbf{a} , the conditional transition probability $T(s', \mathbf{a}, s) = P(s'|s, \mathbf{a})$ describes the distribution over the next state s' and generalize the notion of deterministic dynamics. The Markov property requires that the next state s' and reward depend only on the previous state s and action \mathbf{a} , and not on any other information [15.13]. In robotics, we are able to find an approximate notion of a state in a **MDP** for many situations.

Goals of Reinforcement Learning

The goal of **RL** is to discover an optimal policy π^* that maps states (or observations) to actions so as to maximize the expected return J , which corresponds to the cumulative expected reward. There are different models of optimal behavior [15.165] which result in different definitions of the expected return. A finite-horizon model only attempts to maximize the expected reward for the horizon H , i. e., the next H (time-)steps h

$$J = E \left\{ \sum_{h=0}^H R_h \right\}.$$

This setting can also be applied to model problems where it is known how many steps are remaining.

Alternatively, future rewards can be discounted by a discount factor γ (with $0 \leq \gamma < 1$) yielding a metric

$$J = (1 - \gamma) E \left\{ \sum_{h=0}^{\infty} \gamma^h R_h \right\}.$$

This setting is most frequently discussed in classical **RL** texts. The parameter γ affects how much the future is taken into account and needs to be tuned manually. As illustrated in [15.165], this parameter often qualitatively changes the form of the optimal solution. Policies

designed by optimizing with small γ are myopic and greedy, and may lead to poor performance if we actually care about longer term rewards. It is straightforward to show that the optimal control law can be unstable if the discount factor is too low (e.g., it is not difficult to show this destabilization even for discounted linear quadratic regulation problems). Hence, discounted formulations are occasionally inadmissible in robot control despite that they are somewhat more common in the machine learning community.

In the limit when the discount factor γ approaches 1, the metric approaches what is known as the average-reward criterion [15.7]

$$J = \lim_{H \rightarrow \infty} E \left\{ \frac{1}{H} \sum_{h=0}^H R_h \right\}.$$

This setting has the problem that it cannot distinguish between policies that initially gain a transient of large rewards and those that do not. This transient phase, also called prefix, is dominated by the rewards obtained in the long run. If a policy accomplishes both an optimal prefix as well as an optimal long-term behavior, it is called bias optimal [15.166]. An example in robotics would be the transient phase during the start of a rhythmic movement, where many policies will accomplish the same long-term reward but differ substantially in the transient (e.g., there are many ways of starting the same gait in dynamic legged locomotion) allowing for room for improvement in practical application.

In real-world domains, the shortcomings of the discounted formulation are often more critical than those of the average reward setting as stable behavior is often more important than a good transient [15.167]. We also often encounter an episodic control task, where the task runs only for H time-steps and then reset (potentially by human intervention) and started over. This horizon H may be arbitrarily large, as long as the expected reward over the episode can be guaranteed to converge. As such episodic tasks are probably the most frequent ones, finite-horizon models are often the most relevant.

Two natural goals arise for the learner. In the first, we attempt to find an optimal strategy at the end of a phase of training or interaction. In the second, the goal is to maximize the reward over the whole time the robot is interacting with the world.

In contrast to supervised learning, the learner must first discover its environment and is not told the optimal action it needs to take. To gain information about the rewards and the behavior of the system, the agent needs to explore by considering previously unused actions or actions it is uncertain about. It needs to decide whether to play it safe and stick to well-known actions

with (moderately) high rewards or to dare trying new things in order to discover new strategies with an even higher reward. This problem is commonly known as the *exploration–exploitation tradeoff*. However, as state spaces in robotics problems are often tremendously large due to continuous and high-dimensional state–action spaces, exploring the entire state–action space is mostly infeasible. This problem is often referred to as the *curse of dimensionality* [15.168].

Off-policy methods learn independently of the employed policy, i.e., an explorative strategy that is different from the desired final policy can be employed during the learning process. *On-policy* methods collect sample information about the environment using the current policy. As a result, exploration must be built into the policy and determines the speed of the policy improvements. Such exploration and the performance of the policy can result in an exploration–exploitation tradeoff between long- and short-term improvement of the policy. Modeling exploration models with probability distributions has surprising implications, e.g., stochastic policies have been shown to be the optimal stationary policies for selected problems [15.169, 170] and can even break the curse of dimensionality [15.171]. Furthermore, stochastic policies often allow the derivation of new policy update steps with surprising ease.

The agent needs to determine a correlation between actions and reward signals. An action taken does not have to have an immediate effect on the reward but can also influence a reward in the distant future. The difficulty in assigning credit for rewards is directly related to the horizon or mixing time of the problem. It also increases with the dimensionality of the actions as not all parts of the action may contribute equally.

15.3.3 Optimal Control with Learnt Models

The classical RL setup is a MDP where, additionally, to the states s , actions a , and rewards R we also have transition probabilities $T(s', a, s)$. Here, the reward is modeled as a reward function $R(s, a)$. If both the transition probabilities and reward function are known, this can be seen as an optimal control problem [15.152]. If these functions are acquired from measured data through model learning methods as described in Sect. 15.2, we are in the scenario of *optimal control with learnt models* indicated in Fig. 15.1.

The value function $V^\pi(s)$ provides an assessment of much reward will be accumulated starting from state s and following a given policy π . If a policy is optimal, denoted as π^* , the corresponding optimal value function will be denoted as V^{π^*} , often abbreviated as V^* . For each state there can be one or several optimal

actions a^* , resulting in the *same* value $V^*(s)$. The consistency condition for optimality is

$$V^*(s) = \max_a \left[R(s, a) + \gamma \sum_{s'} V^*(s') T(s, a, s') \right] \quad (15.11)$$

in the discounted case. This statement is equivalent to the *Bellman principle of optimality* [15.168] that states:

An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

Thus, we have to perform an optimal action a^* , and, subsequently, follow the optimal policy π^* in order to achieve a global optimum. This principle of optimality has also been crucial in enabling the field of optimal control [15.172]. Note that for constructing the optimal policy, the max operator in (15.11) needs to be evaluated, which requires knowledge of the state transition model $T(s, a, s')$, i.e., this approach is generically a model-based requiring either a predefined model or a learnt one using insights from Sect. 15.2.

Dynamic programming-based methods are the classical approach for solving optimal control problems in RL. These require, as mentioned before, a model of the transition probabilities $T(s', a, s)$ and the reward function $R(s, a)$ to calculate the value function. These functions do not necessarily need to be predetermined but can also be learned from data, potentially incrementally. Such methods are called *model-based RL* methods or optimal control with learnt models. Typical methods include policy iteration and value iteration.

Policy iteration alternates between the two phases of policy evaluation and policy improvement. The approach is initialized with an arbitrary policy. Policy evaluation determines the value function for the current policy. Each state is visited and its value is updated based on the current value estimates of its successor states, the associated transition probabilities, as well as the policy. This procedure is repeated until the value function converges to a fixed point, which approximates the true value function. Policy improvement greedily selects the best action in every state according to the value function, thus creating a policy update. The two steps of policy evaluation and policy improvement are iterated until the policy does not change any longer.

Policy iteration only updates the policy once the policy evaluation step has converged. In contrast, value iteration combines the steps of policy evaluation and policy improvement by directly updating the value function based on (15.11) every time a state is updated.

15.3.4 Model-Free Value Function Approaches

Many traditional RL approaches are based on identifying (possibly approximate) solutions to this equation, and are known as *value function methods*. Instead of deriving the value functions from a transition model and a reward function, they first approximate the value function, and use it to construct the optimal policy.

Instead of the value function $V^\pi(s)$, these algorithms usually rely on the state–action value function $Q^\pi(s, a)$, which has advantages of determining the optimal policy, as shown below, but also enables the use of model-free methods. This state–action value function is defined as

$$Q^\pi(s, a) = R(s, a) + \gamma \sum_{s'} V^\pi(s') T(s, a, s').$$

In contrast to the value function $V^\pi(s)$, the state–action value function $Q^\pi(s, a)$ explicitly contains the information about the effects of a particular action. The optimal state–action value function is

$$Q^*(s, a) = R(s, a) + \gamma \sum_{s'} \left(\max_{a'} Q^*(s', a') \right) T(s, a, s').$$

If Q^* is known, finding the optimal action just requires finding the maximal value of Q at a given state s – this does not require a model, but is just a standard (although not necessarily trivial) root-finding problem of functions. Importantly, using state–action value function allows a model-free learning approach, at the cost of learning a value function over the joint space of s and a .

If the optimal value function $V^*(s')$ and the transition probabilities $T(s, a, s')$ for the following states are known, determining the optimal policy is straightforward in a setting with discrete actions, as an exhaustive search is possible. For continuous spaces, determining the optimal action a^* is an optimization problem in itself. If both states and actions are discrete, the value function and the policy may, in principle, be represented by tables and picking the appropriate action is reduced to a look-up. For large or continuous spaces, representing the value function as a table becomes intractable. Function approximation is employed to find a lower dimensional representation that matches the real value function as closely as possible, as discussed later.

A wide variety of methods of model-free value function based RL algorithms that attempt to estimate $V^*(s)$ or $Q^*(s, a)$ have been developed and can be split mainly into two classes: (i) rollout-based Monte Carlo

methods and (ii) temporal difference methods such as TD(λ), Q -learning, and SARSA (state-action-reward-state-action).

Monte Carlo methods use sampling in order to estimate the value function. This procedure can be used to replace the policy evaluation step of the dynamic programming-based methods above. Monte Carlo methods are *model-free*, i.e., they do not need an explicit transition function. They perform roll-outs by executing the current policy on the system, hence operating on-policy. The frequencies of transitions and rewards are kept track of and are used to form estimates of the value function. For example, in an episodic setting the state–action value of a given state–action pair can be estimated by averaging all the returns that were received when starting from them.

Temporal difference methods, unlike Monte Carlo methods, do not have to wait until an estimate of the return is available (i.e., at the end of an episode) to update the value function. Rather, they use temporal errors and update at every time step. The temporal error is the difference between the old estimate and a new estimate of the value function, taking into account the reward received in the current sample. These updates are done iteratively and, in contrast to dynamic programming methods, only take into account the sampled successor states rather than the complete distributions over successor states. Like the Monte Carlo methods, these methods are model-free, as they do not use a model of the transition function to determine the value function. For example, the value function could be updated iteratively by

$$V'(s) = V(s) + \alpha [R(s, a) + \gamma V(s') - V(s)],$$

where $V(s)$ is the old estimate of the value function, $V'(s)$ the updated one, and α is a learning rate. This update step is called the TD(0)-algorithm in the discounted reward case. However, in order to select the optimal action, a model of the transition function would still be required, i.e., this method can only be used for policy evaluation in a policy iteration scenario.

The equivalent temporal difference learning algorithm for state–action value functions is SARSA with

$$Q'(s, a) = Q(s, a) + \alpha [R(s, a) + \gamma Q(s', a') - Q(s, a)],$$

where $Q(s, a)$ is the old estimate of the state–action value function and $Q'(s, a)$ the updated one. This algorithm is on-policy as both the current action a as well as the subsequent action a' are chosen according to the current policy π . The average-reward variant is called R -learning [15.173], which is closely related to

Q -learning, with the updates

$$Q'(s, a) = Q(s, a) + \alpha \left[R(s, a) + \gamma \max_{a'} Q(s', a') - Q(s, a) \right].$$

These methods do not require a model of the transition function for determining the deterministic optimal policy $\pi^*(s)$.

15.3.5 Policy Search

Value function approaches infer the optimal policy indirectly by first finding a value function, and then computing the corresponding optimal actions. Instead, the policy can be learned directly, without a detour through a value function. For robotics, this approach has several advantages. It allows for a natural integration of expert knowledge, e.g., through both structure and initializations of the policy. It allows domain-appropriate prestructuring of the policy in an approximate form without changing the original problem. Optimal policies often have many fewer parameters than optimal value functions. For example, in linear quadratic control, the value function has quadratically many parameters in the dimensionality of the state-variables, while the policy requires only linearly many parameters. Local search in policy space can directly lead to good results as exhibited by early hill-climbing approaches [15.172], as well as more recent successes, [15.149, 150, 157, 159–163, 174–182]. Additional constraints can be incorporated naturally, e.g., regularizing the change in the path distribution. As a result, policy search often appears more natural to robotics.

Policy search has been considered the harder problem for a long time as the optimal solution most often cannot directly be determined from equations as in *Bellman principle of optimality* [15.168] and dynamic programming. Nevertheless, in robotics, policy search has recently become an important alternative to value function based methods due to better scalability as well as the convergence problems of approximate value function methods. Most policy search methods optimize locally around existing policies π , parameterized by a set of policy parameters θ_i , by computing changes in the policy parameters $\Delta\theta_i$ that will increase the expected return and results in iterative updates of the form

$$\theta_{i+1} = \theta_i + \Delta\theta_i.$$

The computation of the policy update is the key step here and a variety of updates have been proposed, including pairwise comparisons [15.183, 184], gradient estimation using finite policy differences [15.159, 160, 180, 185–187], general stochastic

optimization methods (such as Nelder-Mead [15.150], cross entropy [15.188] and population-based methods [15.189]), and approaches coming from optimal control such as differential dynamic programming or DDP [15.153] and multiple shooting approaches [15.190].

Let us briefly take a closer look at gradient-based approaches first. The updates of the policy parameters are based on a hill-climbing approach, which is following the gradient of the expected return J for a defined step-size α

$$\theta_{i+1} = \theta_i + \alpha \nabla_{\theta} J.$$

Different methods exist for estimating the gradient $\nabla_{\theta} J$ and many algorithms require tuning of the step-size α .

Finite difference gradient estimators evaluate P policy parameter perturbations to obtain an estimate of the policy gradient. Here, we have $\Delta\hat{J}_p \approx J(\theta_i + \Delta\theta_p) - J_{\text{ref}}$, where $p = [1, \dots, P]$ are the individual perturbations, $\Delta\hat{J}_p$ the estimate of their influence on the return, and J_{ref} is a reference return, e.g., the return of the unperturbed parameters. The gradient can now be estimated by linear regression

$$\nabla_{\theta} J \approx (\Delta\Theta^T \Delta\Theta)^{-1} \Delta\Theta^T \Delta\hat{J},$$

where the matrix $\Delta\Theta$ contains all the stacked samples of the perturbations $\Delta\theta_p$ and $\Delta\hat{J}$ contains the corresponding $\Delta\hat{J}_p$. In order to estimate the gradient the number of perturbations needs to be at least as large as the number of parameters. The approach is very straightforward and even applicable to policies that are not strictly differentiable. However, it is usually considered to be very noisy and inefficient. For the finite difference approach tuning the step-size α for the update, the number of perturbations P , and the type and magnitude of perturbations are all critical tuning factors.

Likelihood ratio methods rely on the insight that in an episodic setting where the episodes τ are generated according to the distribution $P^{\theta}(\tau) = P(\tau|\theta)$ with the return of an episode $J^{\tau} = \sum_{h=1}^H R_h$ and number of steps H in each episode, the expected return for a set of policy parameter θ can be expressed as

$$J^{\theta} = \sum_{\tau} P^{\theta}(\tau) J^{\tau}. \quad (15.12)$$

The gradient of the episode distribution can be written as

$$\nabla_{\theta} P^{\theta}(\tau) = P^{\theta}(\tau) \nabla_{\theta} \log P^{\theta}(\tau), \quad (15.13)$$

which is commonly known as the likelihood ratio or **REINFORCE** (reward increment = nonnegative factor \times offset reinforcement \times characteristic eligibility) [15.191] trick. From multivariate calculus, we have $\nabla_{\theta} \log P^{\theta}(\tau) = \nabla_{\theta} P^{\theta}(\tau) / P^{\theta}(\tau)$. Combining (15.12) and (15.13) we get the gradient of the expected return in the form

$$\begin{aligned}\nabla_{\theta} J^{\theta} &= \sum_{\tau} \nabla_{\theta} P^{\theta}(\tau) J^{\tau} \\ &= \sum_{\tau} P^{\theta}(\tau) \nabla_{\theta} \log P^{\theta}(\tau) J^{\tau} \\ &= E \left\{ \nabla_{\theta} \log P^{\theta}(\tau) J^{\tau} \right\}.\end{aligned}$$

If we have a stochastic policy $\pi^{\theta}(\mathbf{a}|s)$ that generates the episodes τ , we do not need to keep track of the probabilities of the episodes but can directly express the gradient in terms of the policy as $\nabla_{\theta} \log P^{\theta}(\tau) = \sum_{h=1}^H \nabla_{\theta} \log \pi^{\theta}(\mathbf{a}_h|s_h)$. Finally the gradient of the expected return with respect to the policy parameters can be estimated as

$$\nabla_{\theta} J^{\theta} = E \left\{ \left(\sum_{h=1}^H \nabla_{\theta} \log \pi^{\theta}(\mathbf{a}_h|s_h) \right) J^{\tau} \right\}.$$

If we now take into account that rewards at the beginning of an episode cannot be caused by actions taken at the end of an episode, we can replace the return of the episode J^{τ} by the state–action value function $Q^{\pi}(s, \mathbf{a})$ and get [15.161]

$$\begin{aligned}\nabla_{\theta} J^{\theta} &= (1 - \gamma) \\ &\quad \times E \left\{ \sum_{h=1}^H \gamma^h \nabla_{\theta} \log \pi^{\theta}(\mathbf{a}_h|s_h) Q^{\pi}(s_h, \mathbf{a}_h) \right\},\end{aligned}$$

which is equivalent to the *policy gradient theorem* [15.169]. In practice, it is often advisable to subtract a reference J_{ref} , also called baseline, from the return of the episode J^{τ} or the state–action value function $Q^{\pi}(s, \mathbf{a})$, respectively, to get better estimates, similar to the finite difference approach. In these settings, the exploration is automatically taken care of by the stochastic policy.

Initial gradient-based approaches such as finite differences gradients or **REINFORCE** [15.191] have been rather slow. The weight perturbation algorithm is related to **REINFORCE** but can deal with non-Gaussian distributions which significantly improves the signal-to-noise ratio of the gradient [15.180]. Recent natural policy gradient approaches [15.161, 162] have allowed for faster convergence which may be advantageous for

robotics as it reduces the learning time and required real-world interactions.

Alternatives to gradient methods are currently a hot research topic. For example, a different class of safe and fast policy search methods, inspired by expectation-maximization from machine learning, can be derived when the reward is treated as an improper probability distribution [15.192]. Some of these approaches have proven successful in robotics, e.g., reward-weighted regression [15.161], policy learning by weighting exploration with the returns [15.163], Monte Carlo expectation maximization [15.193], and cost-regularized kernel regression [15.194]. Algorithms with closely related update rules can also be derived from different perspectives including policy improvements with path integrals [15.195] and relative entropy policy search [15.175].

Finally, the policy search by dynamic programming [15.196] method is a general strategy that combines policy search with the principle of optimality. The approach learns a nonstationary policy backward in time like dynamic programming methods, but does not attempt to enforce the Bellman equation and the resulting approximation instabilities. The resulting approach provides some of the strongest guarantees that are currently known under function approximation and limited observability. It has been demonstrated in learning walking controllers and in finding near-optimal trajectories for map exploration [15.197].

One of the key open issues in the field is determining when it is appropriate to use each of these methods. Some approaches leverage significant structure specific to the **RL** problem [15.195], including reward structure, Markovianity, causality of reward signals [15.191], and value-function estimates when available [15.161]. Others embed policy search as a generic, black-box, problem of stochastic optimization [15.150, 198–201]. Significant open questions remain regarding which methods are best in which circumstances and further, at an even more basic level, how effective leveraging the kinds of problem structures mentioned above are in practice. Examples of resulting success can be observed in  [VIDEO 354](#) and  [VIDEO 355](#).

Value Function Approaches Versus Policy Search

The discussion whether value function approaches or policy search methods are more suitable for **RL** has been going on for a long time, and, so far, the answer is really problem specific. If a complete optimal value function is known, a globally optimal solution follows by greedily choosing actions that receive the highest value. However, value-function-based approaches have up to now been difficult to scale to high-dimensional

robotics as they require function approximation for the value function – in low dimensions, discretizations and lookup tables work best and have no theoretical issues. Unfortunately, theoretical guarantees from discrete state–action representations no longer hold when employing function approximation. Even finding the optimal action can be a hard problem due to the sensitivity of selecting the optimal action in face of even tiny inaccuracies in the approximated value function, and the cost of solving an optimization problem in a continuous unknown function for action selection. For example, the computational cost of updating a policy in policy search can easily be cheaper than finding just *one* optimal action for one state by searching the state–action value function.

In principle, a value function requires total coverage over the state space and the *largest local error* determines the quality of the resulting policy. A particularly significant problem is the error propagation in value functions. A small change in the policy may cause a large change in the value function, which again causes a large change in the policy. While this may lead more quickly to good, possibly globally optimal solutions, such learning processes often prove unstable under function approximation [15.196, 202, 203] and are considerably more dangerous when applied to real robotic systems where overly large policy deviations may lead to dangerous motor commands.

In contrast, policy search methods usually only consider the current policy and its neighborhood in order to gradually improve performance. The result is that usually only local optima, and not the global one, can be found. However, these methods work well in conjunction with continuous states and actions, and they scale to high-dimensional robots, e.g., humanoid robots.

Policy search methods are sometimes called *actor*-only methods; value function methods are sometimes called *critic*-only methods. The idea of a critic is to first observe and estimate the performance of choosing controls on the system (i. e., the value function), then derive a policy based on the gained knowledge. In contrast, the actor directly tries to deduce the optimal policy. A set of algorithms called *actor-critic* methods attempt to incorporate the advantages of each: a policy is explicitly maintained, as is a value function for the current policy. The value function (i. e., the critic) is not employed for action selection. Instead, it observes the performance of the actor and decides when the policy needs to be updated and which action should be preferred. The resulting update step features the local convergence properties of policy gradient algorithms while reducing update variance [15.204]. There is a tradeoff between the benefit of reducing the variance of the updates and having to learn a value function as the samples required

to estimate the value function could also be employed to obtain better gradient estimates for the update step. *Rosenstein and Barto* [15.205] propose an actor-critic method that additionally features a supervisor in the form of a stable policy.

Function Approximation

The topic of *function approximation* occurs repeatedly in RL and deserves some attention. For discrete state–action problems with not too many states and actions, look-up tables are a reasonable representation for value functions, rewards functions, and state-transitions (i. e., models). But look-up tables have no generalization to neighboring states, which makes them computationally inefficient. Moreover, for continuous state–action problems with many dimensions, discretization would create an exponential growth of the number of discrete states and actions, and is thus infeasible (*curse of dimensionality*). Thus, replacing discretized representations by continuous function approximators is the only possibility.

Function approximation can be employed to represent policies, value functions, and state-transition models. Thus, the techniques discussed in Sect. 15.2.4 also apply to these function approximation problems. However, a fundamental problem in using supervised learning methods developed in the literature for function approximation is that most such methods are designed for independently and identically distributed sample data. However, the data generated by the RL process is usually neither independent nor identically distributed. Usually, the function approximator itself plays some role in the data collection process (e.g., by serving to define a policy that we execute on a robot.)

Linear basis function approximators form one of the most widely used approximate value function techniques in continuous (and discrete) state spaces. This popularity is largely due to the simplicity of their representation as well as a convergence theory, albeit limited, for the approximation of value functions based on samples [15.206]. Let us briefly take a closer look at a radial basis function network to illustrate this approach. The value function maps states to a scalar value. The state space can be covered by a grid of points, each of which correspond to the center of a Gaussian-shaped basis function. The value of the approximated function is the weighted sum of the values of all basis functions at the query point. As the influence of the Gaussian basis functions drops rapidly with the distance of its center, the value of the query points will be predominantly influenced by the neighboring basis functions. The weights are set in a way to minimize the error between the observed samples and the reconstruction. For the mean squared error, these weights can be de-

terminated by linear regression. *Kolter and Ng* [15.207] discuss the benefits of regularization of such linear function approximators to avoid over-fitting.

Other possible function approximators for value functions include wire fitting, which *Baird and Klopff* [15.208] suggested as an approach that makes continuous action selection feasible. Using Fourier basis has been suggested by *Konidaris et al.* [15.209]. Even discretizing the state space can be seen as a form of function approximation where coarse values serve as estimates for a smooth continuous function. One example is tile coding [15.13], where the space is subdivided into (potentially irregularly shaped) regions, called tiling. The number of different tilings determines the resolution of the final approximation. Policy search also benefits from compact representations of the policy.

Models of the system dynamics can be represented using a wide variety of techniques. In this case, it is often important to model the uncertainty in the model (e.g., by a stochastic model or Bayesian estimates of model parameters) to ensure that the learning algorithm does not exploit model inaccuracies. See Sect. 15.3.9 for a more detailed discussion.

15.3.6 Challenges in Robot Reinforcement Learning

Reinforcement learning is generally a difficult problem and many of its challenges are particularly apparent in the robotics setting. As the states and actions of most robots are inherently continuous, we are forced to consider the resolution at which they are represented. We must decide how fine grained the control is that we require over the robot, whether we employ discretization or function approximation, and what time step we establish. Additionally, as the dimensionality of both states and actions can be high, we face the *Curse of Dimensionality* [15.168] as discussed in Sect. 15.3.6, *Curse of Dimensionality*. As robotics deals with complex physical systems, samples can be expensive due to the long execution time of complete tasks, required manual interventions, and the need for maintenance and repair. In these real-world measurements, we must cope with the uncertainty inherent in complex physical systems. A robot requires that the algorithm runs in real-time. The algorithm must be capable of dealing with delays in sensing and execution that are inherent in physical systems (Sect. 15.3.6). A simulation might alleviate many problems but these approaches need to be robust with respect to model errors as discussed later. An often underestimated problem is the goal specification, which is achieved by designing a good reward function. As noted in Sect. 15.3.6, this choice can make

the difference between feasibility and an unreasonable amount of exploration.

Curse of Dimensionality

When *Bellmann* [15.168] explored optimal control in discrete high-dimensional spaces, he faced an exponential explosion of states and actions for which he coined the term *Curse of Dimensionality*. As the number of dimensions grows, exponentially more data and computation is needed to cover the complete state-action space. Evaluating every state quickly becomes infeasible with growing dimensionality, even for discrete states.

Robotic systems often have to deal with these high-dimensional states and actions due to the many degrees of freedom of modern anthropomorphic robots. For example, in a ball-paddling task (VIDEO 355) the proper representation of a robot's state would consist of its joint angles and velocities for each of its seven degrees of freedom as well as the Cartesian position and velocity of the ball (Fig. 15.7). The robot's actions would be the generated motor commands, which often are torques or accelerations. In this example, we have $2 \times (7 + 3) = 20$ state dimensions and seven-dimensional continuous actions.

In robotics, such tasks are often rendered tractable to the robot engineer by a hierarchical task decomposition that shifts some complexity to a lower layer of functionality. Classical RL approaches often consider a grid-based representation with discrete states and actions, often referred to as a *grid-world*. A navigational task for mobile robots could be projected into

Fig. 15.7 State-space used in the modeling of a robot RL task of paddling a ball. This example can also be observed in VIDEO 355

this representation by employing a number of actions like *move to the cell to the left* that use a lower level controller that takes care of accelerating, moving, and stopping while ensuring precision. In the ball-paddling example, we may simplify by controlling the robot in racket space (which is lower dimensional as the racket is orientation-invariant around the string's mounting point) with an operational space control law [15.15]. Many commercial robot systems also encapsulate some of the state and action components in an embedded control system (e.g., trajectory fragments are frequently used as actions for industrial robots). However, this form of a state dimensionality reduction severely limits the dynamic capabilities of the robot according to our experience [15.63, 210].

The RL community has a long history of dealing with dimensionality using computational abstractions. It offers a larger set of applicable tools ranging from adaptive discretizations [15.211] and function approximation approaches [15.13] to macro-actions or options [15.212, 213]. Options allow a task to be decomposed into elementary components and quite naturally translate to robotics. Such options can autonomously achieve a subtask, such as opening a door, which reduces the planning horizon [15.212]. The automatic generation of such sets of options is a key issue in order to enable such approaches. We will discuss approaches that have been successful in robot RL in Sect. 15.3.7.

Curse of Real-World Samples

Robots inherently interact with the physical world and, thus, create their own learning data from physical sensors. Real physical systems create a variety of problems that are worthwhile to keep in mind:

- Robot hardware is usually expensive, suffers from wear and tear, and requires careful maintenance. Repairing a robot system is a nonnegligible effort associated with cost, physical labor, and long waiting periods. To apply RL in robotics, safe exploration becomes a key issue of the learning process [15.157, 214–216].
- The robot and its environment may continually change slowly, e.g., due to wear and tear, or light conditions. Thus, the learning process should be able to track these changing conditions, i. e., learn continually.
- Experimentation with real robots is time consuming, e.g., putting the pole back on the robot's end-effector during pole balancing after a failure, and running many trials for learning. Algorithms that are data efficient are often more important than memory and computations needed to process the data.
- Real-time constraints on an actual robot impose constraints for how much computation can be performed for action generation and learning updates. These constraints are less severe in an episodic setting where the time intensive part of the learning can be postponed to the period between episodes. Hester et al. [15.217] have proposed a real-time architecture for model-based value function RL methods taking into account these challenges.
- Time-discretization, inevitable in computer implementations, can generate undesirable artifacts, e.g., the distortion of distance between states, or smoothing effect by temporal aliasing.
- Delays in information processing with physical sensors and actuators can negatively affect learning. This effect can be addressed by putting some number of recent actions into the state, at the cost of significantly increasing the dimensionality of the problem.

Curse of Under-Modeling and Model Uncertainty

One way to offset the cost of real-world interaction is to use accurate models as simulators as suggested in Sect. 15.2.5. In an ideal setting, this approach would render it possible to learn the behavior in simulation and subsequently transfer it to the real robot. Unfortunately, creating a sufficiently accurate model of the robot and its environment is often impossible. As small modeling errors accumulate over time, the simulated robot can quickly diverge from the real-world system, such that the policy will not transfer without significant modifications as experienced by [15.218]. For tasks where the system is self-stabilizing (i. e., where the robot does not require active control to remain in a safe state or return to it), transferring policies often works much better [15.219]. Learning in simulation, however, becomes quickly useless when contact dynamics and friction are too hard to model. For example, in the ball-paddling task the elastic string that attaches the ball to the racket, and the contact dynamics of the bouncing ball have such modeling problems.

Curse of Goal Specification

In RL, the desired behavior is implicitly specified by the reward function. While often dramatically simpler than specifying the behavior itself, in practice, it can be surprisingly difficult to define a good reward function, such that manual design and tuning become very important. In many domains, it seems natural to provide rewards only upon task achievement – for example, when a table tennis robot wins a match. This view results in an apparently simple, binary reward specification. However, a robot may receive such a reward so rarely that it is un-

likely to ever succeed in its lifetime. Instead of relying on simpler binary rewards, we frequently need to include intermediate rewards in the scalar reward function to guide the learning process to a reasonable solution, a process known as *reward shaping* [15.156]. Additionally, physical constraints of the robot in terms of range of motion and torque saturation need to be taken into account. Often, a change in coordinates, i. e., the question in which space (e.g., task space, joint space) the cost function should be specified, can determine success or failure. In general, RL algorithms are also notorious for exploiting the reward function in ways that are not anticipated by the designer.

Inverse RL, also known as inverse optimal control [15.220], is a promising alternative to specifying the reward function manually. It assumes that a reward function can be reconstructed from a set of expert demonstrations as indicated in Fig. 15.1. This reward function does not necessarily correspond to the true reward function, but provides guarantees on the resulting performance of learned behaviors [15.221, 222]. Inverse RL was initially studied in the control community [15.8] and in the field of economics [15.223]. The initial results were only applicable to limited domains (linear quadratic regulator problems) and required closed form access to plant and controller, hence samples from human demonstrations could not be used. *Russel* [15.220] brought the field to the attention of the machine learning community. *Abbeel* and *Ng* [15.221] defined an important constraint on the solution to the inverse RL problem when reward functions are linear in a set of features: a policy that is extracted by observing demonstrations has to earn the same reward as the policy that is being demonstrated. *Ratliff* et al. [15.222] demonstrated that inverse optimal control can be understood as a generalization of ideas in machine learning of *structured prediction* and introduced efficient subgradient-based algorithms with regret bounds that enabled large scale application of the technique within robotics. *Ziebart* et al. [15.2] extended the technique developed by *Abbeel* and *Ng* [15.221] by rendering the idea robust and probabilistic, enabling its effective use for both learning policies and predicting the behavior of suboptimal agents. These techniques, and many variants, have been recently successfully applied to outdoor robot navigation [15.224–226], manipulation [15.227], and quadruped locomotion [15.224, 227, 228]. An example of a resulting success can be observed in  VIDEO 353.

More recently, the notion that complex policies can be built on top of simple, easily solved optimal control problems by exploiting rich, parametrized reward functions has been exploited within RL more directly. In [15.229, 230], complex policies are derived

by adapting a reward function for simple optimal control problems using policy search techniques. *Zucker* and *Bagnell* [15.230] demonstrate that this technique can enable efficient solutions to robotic marble-maze problems that effectively transfer between mazes of varying design and complexity. These works highlight the natural tradeoff between the complexity of the reward function and the complexity of the underlying RL problem for achieving a desired behavior.

15.3.7 Tractability Through Representation

Much of the success of RL methods has been due to the clever use of approximate representations. The need of such approximations is particularly pronounced in robotics, where table-based representations (as discussed in Sect. 15.3.4) are rarely scalable. Common themes are to reduce the dimensionality of states and actions, to choose representations that are robust in face of the data generation process of RL, or to find compact parameterizations of policies and value functions. The following outlines a list of items that are relevant:

- A variety of authors have manually developed discretizations so that basic tasks can be learned on real robots. For low-dimensional tasks, we can generate discretizations straightforwardly by splitting each dimension into a number of regions. The main challenge is to find the right number of regions for each dimension that allows the system to achieve a good final performance while still learning quickly. Example applications include balancing a ball on a beam [15.231], one degree of freedom ball-in-a-cup [15.232], two degree of freedom crawling motions [15.233], and gait patterns for four-legged walking [15.234]. Complex tasks need much more hand crafting, e.g., as in navigation [15.235], vision-based processing [15.236], or RoboCup scenarios [15.237].
- Adaptive representations can be very useful, e.g., as in cooperative task achievement [15.238], or computer vision [15.239].
- Automatic construction of meta-actions (and the closely related concept of options) has fascinated RL researchers. The idea is to have more intelligent actions that are composed of a sequence of commands and that in themselves achieve a simple task. A simple example would be to have a meta-action *move forward 5 m*. For example, in [15.240], the state and action sets are constructed in such a way that repeated action primitives lead to a change in the state to overcome problems associated with the discretization. *Huber* and *Gruppen* [15.241] use a set of controllers with associated predicate states as

a basis for learning turning gates with a quadruped. *Fidelman* and *Stone* [15.242] use a policy search approach to learn a small set of parameters that controls the transition between a walking and a capturing meta-action in a RoboCup scenario. A task of transporting a ball with a dog robot [15.243] can be learned with semiautomatically discovered options. Using only the subgoals of primitive motions, a humanoid robot can learn a pouring task [15.244]. Other examples include foraging [15.245] and cooperative tasks [15.246] with multiple robots, grasping with restricted search spaces [15.247], and mobile robot navigation [15.248]. If the meta-actions are not fixed in advance, but rather learned at the same time, these approaches are hierarchical RL approaches. *Konidaris* et al. [15.249, 250] propose an approach that constructs a skill tree from human demonstrations. Here, the skills correspond to options and are chained to learn a mobile manipulation skill.

- In a relational representation, the states, actions, and transitions are not represented individually. Entities of the same predefined type are grouped and their relationships are considered. This representation may be preferable for highly geometric tasks (which frequently appear in robotics) and has been employed to learn to navigate buildings with a real robot in a supervised setting [15.251] and to manipulate articulated objects in simulation [15.252].
- Function approximation has always been the key component that allowed value function methods to scale into interesting domains. Unfortunately, the max-operator used within the Bellman equation and temporal-difference updates can theoretically make most linear or nonlinear approximation schemes unstable for either value iteration or policy iteration. Quite frequently such an unstable behavior is also exhibited in practice. Linear function approximators are stable for policy evaluation, while nonlinear function approximation (e.g., neural networks) can even diverge if just used for policy evaluation [15.206]. A large number of approaches have been suggested to facilitate value function approximation. For instance, creating physics-inspired features as nonlinear basis functions for linear approximator [15.151, 253] can be promising. Generic neural networks can be successful [15.254, 255], in particular the *CMAC* (cerebellar model articulation controller) neural network [15.256]. Local model function approximators often provide more stable learning behavior [15.151, 257, 258]. Probabilistic nonparametric function approximators like Gaussian process regression has recently shown interesting successes in robot RL [15.259–262].

- Similar to choosing a good structure in value function approximation, choosing a good structure and parameterization for the policy can make a big difference for success or failure of RL. Finding sparse parameterization essentially reduces the dimensionality of the learning problem, as only a few parameters need to be learned, and not an action for every time step. Among the most popular have been spline-based parameterizations [15.158, 180, 199], linear parameterizations based on physics-inspired features [15.263], parameterized motor primitives [15.161, 162, 264, 265], Gaussian Mixture Models [15.157, 177, 266], generic neural networks [15.149, 176, 185], and nonparametric approaches [15.175, 194].

15.3.8 Tractability Through Prior Knowledge

Prior knowledge can dramatically help guide the learning process. It can be included in the form of initial policies, demonstrations, initial models, a predefined task structure, or constraints on the policy such as torque limits or ordering constraints of the policy parameters. These approaches significantly reduce the search space and, thus, speed up the learning process. Providing a (partially) successful initial policy allows a RL method to focus on promising regions in the value function or in policy space. Prestructuring a complex task such that it can be broken down into several more tractable ones can significantly reduce the complexity of the learning task. Constraints may also limit the search space, but often pose new, additional problems for the learning methods. For example, policy search limits often do not handle hard limits on the policy well. Relaxing such constraints (a trick often applied in machine learning) is not feasible if they were introduced to protect the robot in the first place.

As indicated in Fig. 15.1, observed expert data can be used for constructing useful policies. Using demonstrations to initialize RL has become rather popular and provides multiple benefits. Perhaps the most obvious benefit is that it provides supervised training data of what actions to perform in states that are encountered. Such data may be helpful when used to bias policy action selection. The most dramatic benefit, however, is that demonstration – or a hand-crafted initial policy – removes the need for *global exploration* of the policy or state-space of the RL problem. The student can improve by locally optimizing a policy knowing what states are important, making local optimization methods feasible. Of course, if the demonstration was not close to the globally optimal behavior, only local optima can be discovered.

Fig. 15.8 Boston Dynamics LittleDog jumping (after [15.178], courtesy of Zico Kolter)

Demonstrations by a teacher can be obtained in two different scenarios. In the first, the teacher demonstrates the task using his or her own body; in the second, the teacher controls the robot to do the task. The first scenario is limited by the embodiment issue, as the movement of a human teacher usually cannot be mapped directly to the robot due to different physical constraints and capabilities. For example, joint angles of a human demonstrator need to be adapted to account for the kinematic differences between the teacher and the robot. Often it is more advisable to only consider task-relevant information, such as the Cartesian positions and velocities of the end-effector and the object. Demonstrations obtained by motion capture have been used to learn a pendulum swingup [15.174], ball-in-a-cup [15.267], and grasping [15.260].

The second scenario obtains demonstrations by a human teacher directly controlling the robot. Here the human teacher first has to learn how to achieve a task with the particular robot's hardware, adding valuable prior knowledge. If the robot is back-drivable, kinesthetic teach-in (i.e., by taking it by the hand and moving it) can be employed, which enables the teacher to interact more closely with the robot. This method has resulted in applications including T-ball batting [15.161, 162], reaching tasks [15.177, 268], ball-in-a-cup [15.163] and  VIDEO 355, flipping a light switch [15.269], playing pool and manipulating a box [15.270], and opening a door and picking up objects [15.271]. A marble maze task can be learned using demonstrations by a human player [15.272].

Often a task can be decomposed hierarchically into basic components or into a sequence of increasingly difficult tasks. In both cases the complexity of the learning task is significantly reduced. For example, hierarchical Q -learning has been used to learn different behavioral levels for a six-legged robot: moving single legs, locally moving the complete body, and globally moving

the robot toward a goal [15.273]. A stand-up behavior considered as a hierarchical RL task has been learned using Q -learning in the upper-level and a continuous actor-critic method in the lower level [15.274]. Navigation in a maze can be learned using an actor-critic architecture by tuning the influence of different control modules and learning these modules [15.275]. Huber and Grupe [15.241] combine discrete event system and RL techniques to learn turning gates for a quadruped. Hart and Grupe [15.213] learned to bi-manual manipulation tasks by assembling policies hierarchically. Daniel et al. [15.276] learn options in a tetherball scenario and Muelling et al. [15.147] learn different strokes in a table tennis scenario ( VIDEO 354). Whitman and Atkeson [15.277] show that the optimal policy for some global systems (like a walking controller) can be constructed by finding the optimal controllers for simpler subsystems and coordinating these.

As discussed in Sect. 15.3.2, balancing exploration and exploitation is an important consideration. Task knowledge can be employed to guide robots curiosity to focus on regions that are novel and promising at the same time. For example, a mobile robot learns to direct attention by employing a modified Q -learning approach using novelty [15.278]. Using *corrected truncated returns* and taking into account the estimator variance, a six-legged robot employed with stepping reflexes can learn to walk [15.279]. Offline search can be used to guide Q -learning during a grasping task [15.280]. Using upper confidence bounds [15.281] to direct exploration into regions with potentially high rewards, grasping can be learned efficiently [15.262].

15.3.9 Tractability Through Models

In Sect. 15.3.2, we discussed robot RL from a model-free perspective where the system simply served as a data generating process. Such model-free reinforce-

ment algorithms try to directly learn the value function or the policy without any explicit modeling of the transition dynamics. In contrast, many robot RL problems can be made tractable by learning forward models, i.e., approximations of the transition dynamics based on data. Such model-based RL approaches jointly learn a model of the system with the value function or the policy and often allow for training with less interaction with the real environment. Reduced learning on the real robot is highly desirable as simulations are frequently faster than real-time while safer for both the robot and its environment. The idea of combining learning in simulation and in the real environment was popularized by the Dyna-architecture [15.282], prioritized sweeping [15.283], and incremental multi-step Q -learning [15.284] in RL. In robot RL, the learning step on the simulated system is often called *mental rehearsal*.

A few remarks concerning model-based RL are important. It is essentially impossible to obtain a forward model that is accurate enough to simulate a complex real-world robot system without error. Reinforcement learning approaches exploit such model inaccuracies if they are beneficial for the reward received in simulation [15.174]. The resulting policies may work well with the forward model (i.e., the simulator) but poorly on the real system. This effect is known as simulation bias.

Nevertheless, simulation biases can be addressed by introducing stochastic models or distributions over models even if the system is very close to deter-

ministic. Artificially adding a little noise will smooth model errors and avoid policy over-fitting [15.153, 285]. Model learning methods that maintain probabilistic uncertainty about true system dynamics allow the RL algorithm to generate distributions over the performance of a policy. Such methods explicitly model the uncertainty associated with the dynamics at each state and action. For example, when using a Gaussian process model of the transition dynamics, a policy can be evaluated by propagating the state and associated uncertainty forward in time. Such evaluations in the model can be used by a policy search approach to identify where to collect more data to improve a policy, and may be exploited to ensure that control is safe and robust to model uncertainty [15.150, 214]. When the new policy is evaluated on the real system, the novel observations can subsequently be incorporated into the forward model. *Bagnell* and *Schneider* [15.150] showed that maintaining model uncertainty and using it in the inner-loop of a policy search method enabled effective flight control using only minutes of collected data, while performance was compromised by considering a best-fit model. This approach uses explicit Monte Carlo simulation in the sample estimates. By treating model uncertainty as if it were noise [15.214] as well as employing analytic approximations of forward simulation, a cart-pole task can be solved with less than 20s of interaction with the physical system [15.157]; a visually driven block-stacking task has also been learned data-efficiently [15.164].

15.4 Conclusions

We focussed on the two key branches of robot learning, i.e., supervised learning of internal models with regression methods, and trial-and-error with reinforcement learning. While both topics are traditional topics of machine learning, inserting these learning topics into *robot learning* adds a variety of complexities and intricacies, which are not immediately obvious – indeed many issues have been revealed only through experiments with physical robots. A large number of issues are control theoretic, i.e., due to dealing with a closed-loop physical system that needs to be stable. Other issues are due to the inherent constraints that a physical system imposes, e.g., actuator saturation and the limits of the work space. High-dimensional continuous state–action space causes yet another set of problems, and particularly affects feasibility and efficiency of robot learning. Model-errors and sensor noise can have ad-

verse outcome on the learning process. And the fact that a robot needs to generate its own learning data, i.e., the exploration–exploitation tradeoff and ever changing sampling distributions, creates a large number of problems.

We note that there is no clear recipe for robot learning, but rather a large number of ingredients that, when used appropriately, can achieve excellent learning results. As a caveat, even minor incorrect choices can completely prevent any success of learning. That robot learning has yet not reached maturity is obvious from the fact that learning algorithms are rarely used on robots on a daily basis – most results are feasibility studies and not robust enough for daily use. Many results are also overtuned to a particular physical robot, and do not generalize to others easily.

Some of the open questions for the future of robot learning include:

- How to choose appropriate representations automatically for model learning, value function learning, and policy learning? Perhaps, there is one particular choice that robustly works for many different robots, or maybe one could find a small set of possible approaches that can easily be compared.
- How to create useful reward functions? This topic connects to inverse RL, and on a higher level to how to understand the intentions of observed behavior.
- How much can prior knowledge help? How much is needed? How should it be provided?
- How to integrate more tightly with perception? Robot learning is largely *action-centric* and assumes that *perception* is provided. In reality, there is a perception-action-learning loop where the different components interact significantly, and need to be jointly developed.
- How to reduce parameter sensitivity? Manual tuning of hyperparameters such as gradient rates, for-

getting rates, exploration rates, etc., are a common curse for the robot learning practitioner, and often, a small change in a parameter determines success or failure.

- How to robustly deal with modeling errors? Models are great when they work, but disastrous if they are not accurate enough. Probabilistic and robust control methods may help, but can also degrade performance due to very conservative learning results.

This list is by no means exhaustive, but captures some of the key issues. In the end, there is strong need for researchers and scientists who are willing to tackle a complex mixture of theoretical problems and experimental problems. Often, just setting up an experimental robot environment with accurate and efficient debugging and visualization tools is a formidable effort. Then, finding the right experiment and the right data trace that allows for error diagnosis in robot learning is still a bit of an art and requires fairly deep insights into physics, algorithms, software architectures, and technology.

Bradley J. Nelson, Zurich, Switzerland
Lixin Dong, East Lansing, USA
Fumihito Arai, Nagoya, Japan

The chapters contained in **Part B**, Design, are concerned with the design and modeling of the actual physical realizations of a robot. Some of the more obvious mechanical structures that come to mind are arms, legs, and hands. To this list we can add wheeled vehicles and platforms; snake-like and continuum robots; robots capable of swimming and flying; and robot structures at the micro- and nanoscales. Even for that most basic robotic device, the arm, an incredibly diverse set of structures is possible, depending on the number and types of joints and actuators, and the presence of closed loops in the kinematic structure, or flexibility in the joints and links. Constructing models, and planning and control algorithms for these diverse structures represents an even greater set of challenges.

The topics addressed in these chapters are essential to creating not only the physical robot itself, but also to creating and controlling movements, and manipulating objects in desired ways. As such the connections with the chapters on Robot Foundations (Part A) – particularly the chapters on Kinematics (Chap. 1), Dynamics (Chap. 2), and Mechanisms and Actuation (Chap. 3) – are self-evident. What ultimately distinguishes robotics from other disciplines that study intelligence is that, by definition, robots require a physical manifestation, and by extension must physically interact with the environment. In this regard the topics addressed in these chapters can be said to constitute the most basic layer of this endeavor.

Just as it is difficult to examine human intelligence from a purely abstract perspective, remotely detached from the physical body, so it is difficult to separate the contents of the remaining parts without including in the discussion the actual medium of interaction with the physical world, the (physical) robots themselves. For example, the question of how to coordinate sensing and perception with action (Part C), how to grasp and manipulate objects (Part D), and how to teach robots to move in the world (Part E), must inevitably consider the physical structure of the robot. Robots specialized to various applications and environments (Part F), particularly those intended for direct interaction with humans (Part G), naturally must also consider the robot's physical structure.

With this overview of Part B, we now provide a brief synopsis of each chapter.

Chapter 16, Performance Evaluation and Design Criteria, provides a concise overview of the robot design process, and surveys some of the criteria and tools used in the mechanical design and performance evaluation of robots. Criteria such as workspace volume, local and global dexterity, and elastostatic and elastodynamic

performance are not only applicable to determining the topological structure and physical dimensions of the robot, but can also be useful for, e.g., workpiece placement and kinematic redundancy resolution.

Chapter 17, Limbed Systems, discusses the myriad issues involved in the design, analysis, and control of robots with limbs. Defining a limbed system as a robot consisting of a body and at least one limb such that it is able to support and propel itself, the chapter begins with an overview of the design process for limbed systems, from conceptual to detailed, and the basic dynamics of passive and controlled walking. The chapter also examines numerous case studies illustrating the diversity of limbed robot designs, and schemes for their actuation and locomotion. Multi-legged robots, such as dynamic quadrupeds inspired by mammals and behavior-based multilegged robots, are also discussed, as are hybrid leg-wheel-arm robots, tethered walking robots, and even legged robots capable of climbing walls.

Chapter 18, Parallel Mechanisms and Robots, presents an introduction to the kinematics and dynamics of parallel mechanisms such as the well-known Stewart–Gough platform. Parallel mechanisms contain closed loops in their kinematic structure, and as such methods for their analysis differ considerably from those for their serial counterparts. This chapter discusses topics ranging from type synthesis and forward and inverse kinematic solutions of parallel mechanisms, to an investigation of their singularity behavior, workspace characterization, static and dynamic analysis, and practical issues in their design.

Chapter 19, Robot Hands, investigates the principal issues behind the design, modeling, and control of robot hands. Beginning with a discussion of levels of anthropomorphism, and the characterization of robot hand dexterity, the chapter investigates the relevant design issues for robot hands, actuation and transmission architectures, and available sensing technologies. The dynamic modeling and control of robot hands are made challenging not only by the complex kinematic structure, but also by the flexible transmission elements, and the chapter devotes particular attention to these issues.

Chapter 20, Snake-Like and Continuum Robots, begins with a history of snake robots, starting with the pioneering work of Shigeo Hirose in the early 1970s. While snake-like and continuum robots have very similar exterior appearances, there is considerable diversity in their mechanical design, and the ways in which they are actuated. This chapter describes the mechanical design, actuation, modeling, motion planning, and control of such robots. The chapter also provides case studies of a wide range of existing snake-like and continuum

robots that illustrate the diversity of designs as well as applications.

Chapter 21, Soft Robots, begins with the premise that robots of the future will not resemble the bulky rigid machines found in today's factory floors, but will be compliant and adaptable, and able to safely interact with humans – in other words, soft. This chapter discusses the design, modeling, and control of actuators for this new generation of soft robots. The chapter surveys the different principles and technologies that can be used to design and implement actuators for soft robotics. Many of the concepts are organized so as to allow a direct analogy with natural muscles. Variable impedance actuators are examined in some detail, from their mathematical modeling to motion and force planning and control.

Chapter 22, Modular Robots, provides an overview of the design of modular robots. The chapter begins with a discussion of the concept of modularity, and a definition and classification of modular robots. The chapter then examines reconfigurable modular manipulators, from the earliest designs that were conceived in an industrial automation setting, to more recent self-reconfigurable modular robots. Issues related to the design of modules and the interfaces between them, and the determination of optimal configurations, are also discussed in this chapter.

Chapter 23, Biomimetic Robots, broadly examines the ways in which biological principles can be applied to the design of robotic mechanisms. The challenges of biomimetic design include developing a deep understanding of the relevant natural system, and translating this understanding into a set of engineering design rules; this often entails the development of novel fabrication and actuation to realize the biomimetic design. This chapter discusses the basic design principles underlying biomimetic robots and their contrast with bio-inspired robots, and the fundamental components for developing a biomimetic robot. The chapter also provides detailed reviews of biomimetic designs that have been developed for flapping-wing flight, jumping, crawling, wall climbing, and swimming, as well as the enabling material and fabrication technologies for these biomimetic designs.

Chapter 24, Wheeled Robots, provides a general and comprehensive description of wheeled mobile robots. The chapter begins with a discussion of robot

mobility based on the types of wheels and the nature of the kinematic constraints, followed by a classification of wheeled robot structures according to the number and type of wheels and how they are arranged. Omnimobile robots and articulated robot realizations are described, and wheel–terrain interaction models for computing contact forces are also presented. The chapter concludes with a classification of wheel–terrain interaction cases depending on the relative stiffnesses of the wheel and terrain, and the structure and dynamics of suspension systems that enable movement of wheeled robots over uneven surfaces.

Chapter 25, Underwater Robots, examines the design issues for underwater robots, with a focus on remotely operated vehicles and autonomous underwater vehicles. The major components of an underwater robot – from the mechanical elements and subsystems including any attached manipulators, to power sources, actuators and sensors, and architectures for computing and communications and control, are discussed in this chapter. Aspects of the mathematical modeling and control of underwater robots is covered in a separate chapter later in this handbook.

Chapter 26, Flying Robots, provides an overview of the core elements of flying robots. The reader will be guided through the design process of aerial robots, beginning with a qualitative characterization of the different types of flying robot. Design and modeling are particularly closely intertwined in flying robots, and the chapter provides an overview of the underlying aerodynamics and tools for their analysis. The chapter then shows how these tools can be applied to the design and analysis of various types of flying robots, including fixed-wing, rotary-wing, and flapping wing systems, with case studies illustrating these design principles.

Chapter 27, Micro/Nanorobots, provides an overview of the state of the art in micro- and nanorobotics. The former entails robotic manipulation of objects with dimensions in the millimeter to micrometer range, as well as the design and fabrication of autonomous robotic agents within this size range (nanorobotics is defined in the same way, but for dimensions smaller than a micrometer). The chapter outlines scaling effects, actuation, and sensing and fabrication at these scales, and also applications to microassembly, biotechnology, and the construction and characterization of micro- and nano-electromechanical systems.

16. Design and Performance Evaluation

Jorge Angeles, Frank C. Park

In this chapter we survey some of the tools and criteria used in the mechanical design and performance evaluation of robots. Our focus is on robots that are (a) primarily intended for manipulation tasks and (b) constructed with one or more serial kinematic chains. The kinematics of parallel robots is addressed in detail in Chap. 18; their elastostatics is the subject of Sect. 16.5.1. Wheeled robots, walking robots, multifingered hands, and robots intended for outdoor applications, i. e., those encompassing what is known as *field robotics*, are studied in their own chapters; here we provide an overview of the main classes of these robots as relating to design.

16.1	The Robot Design Process	400
16.2	Workspace Criteria	401
16.2.1	Reaching a Set of Goal Frames	403

16.5.2	Mobile Robots	414
16.5.3	Aquatic Robots	415
16.5.4	Flying Robots	416
16.6	Summary	416
	References	416

The most obvious application of the criteria and tools described in this chapter is in the mechanical design of a robot. Robot design differs from the design of 1-degree-of-freedom (DOF) machinery in that the latter is intended for one specific task, e.g., picking up a workpiece from a belt conveyor and placing it on a magazine. Moreover, the conveyor is synchronized with the manipulating machine and the magazine is stationary, with well-defined locations where each workpiece is to be placed. Manipulation robots, in contrast, are not in-

tended for one specific task, but rather for a *family of tasks* falling within one class of workpiece motions, e.g., planar, spherical, translational, or motions produced by systems of the selective compliance assembly robot arm (SCARA) type, also known as *Schönflies displacements* [16.1]. The challenge that robot designers face is therefore one of *uncertainty* in the specific task that the robot will be required to execute. Design criteria have been devised to help the designer cope with uncertainty, as discussed herein.

16.1 The Robot Design Process

Given a family of tasks that constitute the *functional requirements* in the design process, besides more-detailed *design specifications*, the role of the designer consists in producing a robot that will meet all the requirements and specifications. The various stages in the robot design job at hand are intended to:

1. Determine the *topology* of the kinematic chain underlying the mechanical structure. Under this item we consider first the robot type: serial, parallel or hybrid. Then, a decision is to be made on the layout of the various *subchains* in terms of the type of joints, most commonly, revolute and prismatic. Recently, one additional type has been recognized to be equally useful, the Π -joint, coupling two links under relative translation by means of two other links undergoing identical angular displacements, although about different parallel axes. The four links form a parallelogram four-bar linkage [16.2].
2. Determine the *geometric dimensions* of the various links defining the *robotic architecture*, as required to fill a table of *Denavit–Hartenberg (DH) parameters* [16.3] so as to satisfy workspace requirements. Although these parameters are usually understood to include the joint variables, these variables do not affect the *robot architecture*; they determine instead the *robot posture*.
3. Determine the structural dimensioning of the various links and joints, as needed to meet static load requirements, where load includes both forces and moments – wrenches – under either the most demanding or the most likely operation conditions, depending on the design philosophy adopted at the outset.
4. Determine the structural dimensioning of the various links and joints, as needed to meet dynamic load requirements, where loads are inertia effects of links and manipulated object.
5. Determine the elastodynamic dimensioning of the overall mechanical structure, including the actuator dynamics, to avoid a specific spectrum of excitation frequencies under either the most demanding or the most likely operation conditions.
6. Select the actuators and their mechanical transmissions for the operation conditions adopted at the outset to cope with task uncertainty.

The above stages can be performed sequentially, in the order given above: (i) first, the topology is determined based on the family of tasks specified at the outset and the *shape* of the workspace, as discussed in

Sect. 16.2.2; (ii) the link geometry is defined based on the workspace requirements, which include the *maximum reach*, and the topology defined in stage 1; (iii) with the link geometry thus defined, the structural dimensioning of links and joints (unless the robot under design is parallel, which does not fall within the scope of this chapter, all joints are actuated) is undertaken, so as to support the static loads assumed at the outset; (iv) with the links and joints dimensioned for static-load conditions, the link centers of mass and link inertia matrices are determined for a preliminary evaluation of the motor torque requirements (this evaluation is preliminary in that it does not consider the dynamic load brought about by the actuators; this load can be significant, even in the case of parallel robots, which can have all their motors fixed to the robot base); (v) with the links assumed rigid, joint stiffness is assumed, based on experience or using data from a similar robot, which then leads to an elastodynamic model whose natural modes and frequencies can be determined at a selected set of robot postures (dynamic behavior of the structure is dependent on robot posture) by means of scientific code such as Matlab or computer-aided engineering (CAE) code such as CATIA, Siemens PLM, Pro/Engineer or ANSYS; and (vi) if the frequency spectrum of the robot structure is acceptable, the designer can continue to motor selection; otherwise, a redimensioning is required, which means returning to stage 3.

Even though a design cycle can be completed as outlined above, the designer must now incorporate into the elastodynamic model the structural and inertial data provided by the motor manufacturer. This requires a return to stage 5 and a new elastodynamic analysis. It is thus apparent that the robot design process has one element in common with engineering design in general: both are iterative and open-ended [16.4]. Remarkably, however, the various items driving each design stage are, to a large extent, independent of each other, e.g., topology and geometry can be determined independently from motor selection. Obviously, all issues interact in the overall design process, but, within certain design specifications, the various items do not contradict each other, as to warrant a multiobjective design approach. That is, the optimum design of serial robots can be accomplished fairly well by means of a sequence of single-objective optimization jobs. Again, the results of the last stage, motor selection, must be integrated into an overall mathematical model to test the overall performance. One reference addressing practical optimization issues in the conceptual design of industrial robots is [16.5].

Only when the physical limits of components have been exhausted may a radical redesign requiring a return to stage 1 be warranted. This is the case with SCARA systems. Current industrial robots of this class bear topologies that are largely of the serial type, but some parallel SCARA systems have now appeared in the market. Indeed, the quest for shorter cycle time, as pertaining to an industry test cycle – described in Sect. 16.2.1 – has prompted the industry to look for alternatives to serial architectures. This is how ABB Robotics developed a hybrid parallel-serial robot, the *FlexPicker*, built upon *Clavel's* Delta robot [16.6], to which a fourth axis has been added in series with the first three. The latter are laid out in a symmetric, parallel architecture that enables Delta to produce pure translations of its moving platform. Adept Technology's Quattro s650H is reportedly capable of three cycles/s for the same test cycle.

16.2 Workspace Criteria

The most obvious consideration in designing a robot is that its workspace has a set of *required characteristics*. This is a fundamental problem in classical mechanism design, and raises the obvious question of how a user can specify those characteristics.

Issues to consider here pertain, mostly, to what Vijaykumar et al. [16.7] termed the *regional structure* of a manipulator. This applies to manipulators with a *decoupled architecture*, whose last three revolute joints have concurrent axes, thereby forming a *spherical wrist*, the point of concurrency being the *wrist center*. The manipulation task of architectures of this kind thus allows for a *decoupling* of the positioning and the orientation subtasks: the regional structure, consisting of the first three joints, is first postured so as to locate the center of its wrist at a specified point $C(x, y, z)$; then, the *local structure*, i.e., the wrist, is postured so as to make the end-effector (EE) attain a specified orientation with respect to a frame fixed to the base, given by a rotation matrix.

Most algorithms reported in the literature to determine the workspace of a given robot refer to the workspace of the regional structure. Here, we should distinguish between the workspace of the kinematic chain, regardless of the physical implementation of the chain, and that of the physical robot. In the former, all revolute joints are capable of unlimited rotations about their axes; in the latter, joint limits are needed, for example, to avoid wire entanglement. In the early stages of robot design, joint limits need not be con-

This chapter is organized according to the various stages of the robot design process outlined earlier. Noting that topology selection and geometric dimensioning are tightly coupled in the kinematic design process, we first begin with an examination of workspace criteria: we review methods for determining the topology of the kinematic chain, followed by the geometric dimensions so as to satisfy workspace requirements. We then review in detail the various criteria developed for characterizing a robot's manipulating capability, focusing on quantitative notions of dexterity based on both kinematic and dynamic models. We then examine methods for structural dimensioning of the links and joints so as to meet both static and dynamic load requirements. Finally, we discuss elastodynamic dimensioning, and actuator and gear sizing, taking into account properties such as the natural frequency of the robot, and force and acceleration capability requirements. We end the chapter with an overview of mobile, aquatic, and flying robots.

sidered, the workspace thus exhibiting symmetries that are proper of the type of joints of the regional structure. If the first joint is a revolute, the workspace has an axis of symmetry, namely, the axis of this revolute joint; if the first joint is prismatic, the workspace has an extrusion symmetry, with the direction of extrusion given by the direction of motion of this joint. As prismatic joints are infinitely extensive, so is the kinematic workspace of a robot with a prismatic joint. The kinematic workspaces of robots with prismatic joints are usually displayed for a finite portion of this workspace.

In the case of parallel robots, to be studied in full detail in Chap. 14, the regional structure is elusive, in general. The usual practice when displaying the workspace for these robots is to assume a constant orientation of the moving plate, the counterpart of the EE of serial robots [16.8]. A common architecture of parallel robots, which arises quite naturally in the design process, entails identical legs symmetrically placed both on the base platform and on the moving platform. Each leg is, in turn, a serial kinematic chain with one or two active joints, all others being passive. The workspace of this kind of robots also exhibits certain symmetries, but no axial symmetry. The symmetries are dictated by the number of legs and the types of actuated joints.

Coming back to serial robots, the workspace can be defined by an envelope that is essentially of one of two types, either a manifold or a surface that is

smooth *almost everywhere*, i. e., smooth everywhere except for a set of points of *measure zero* in the Lebesgue sense [16.10]. Broadly speaking, a set of measure zero on a surface is a curve, e.g., a meridian on a sphere, or a set of isolated points on a line, e.g., the set of rational numbers on the real line. A paradigm for this second kind of workspace is that of the Puma robot, whose kinematic chain is displayed in Fig. 16.1. In this figure, the regional and the local structures are clearly distinguished, the former being *fully extended*. The workspace of this robot is obtained upon locking all joints but the second, when the robot is in the posture shown in Fig. 16.1. Then, the second joint is fully rotated about its axis, the center C of the wrist then describing a circle of radius R equal to the distance of C from the line L_2 , the plane of the circle being normal to this line and lying a distance b_3 from the axis L_1 of the first joint. This distance is known as the *shoulder offset*. Now, with all joints locked again, but this time with the first joint unlocked, the robot

Fig. 16.1 A Puma robot in a fully stretched posture (after [16.9])

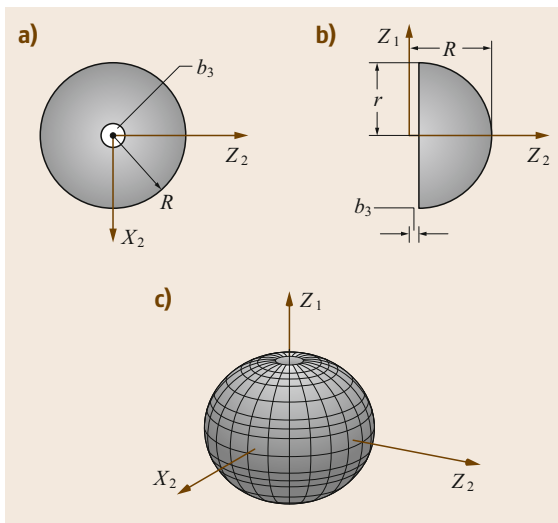

Fig. 16.2 The workspace of a Puma robot (after [16.9])

is turned as a rigid body about L_1 . The result is the toroid of Fig. 16.4. Notice that the solid enclosed by this surface is the result of the Boolean operation $S - C$, where S is the sphere of radius R centered at point O_2 of Fig. 16.1, while C is the infinite cylinder of radius b_3 and axis L_1 , which appears as Z_1 in Fig. 16.2. It is noteworthy that, although this workspace can be readily generated by a simple Boolean operation, it cannot possibly be generated by an implicit function of the form $f(x, y, z) = 0$ because the surface is not a manifold.

Robots with manifold workspaces are not common in industry. We display in Fig. 16.3 an architecture for the regional structure of a six-axis decoupled robot, with its neighboring axes mutually orthogonal and at the same distance a from each other. The common normals to the two pairs of axes, X_2 and X_3 , also lie at the same distance a , as do X_4 from X_3 and C from Z_3 . Point C is the center of the spherical wrist, the latter not being included in the figure. The workspace of this robot admits a representation of the form $f(x, y, z) = 0$ [16.9], which produces the manifold workspace of Fig. 16.4. The shaded internal region of the workspace includes all points admitting four real inverse-kinematics solutions, all other points admitting only two.

Given that any point of the workspace boundary represents a positioning singularity – different from an orientation singularity – manipulators with workspace boundaries that are not manifolds exhibit double singularities at the edges of their workspace boundary, which means that at edge points the rank of the robot Jacobian becomes deficient by two. At any other point of the workspace boundary the rank deficiency is by one.

Fig. 16.3 An orthogonal three-revolute robot (after [16.9])

Design rules based on the *shape* of the workspace can now be drawn:

1. If the workspace required is axially symmetric and finite, use a serial robot with a regional structure composed of revolute joints only.
2. If the workspace required has a symmetry of extrusion and is unbounded, use a serial robot with regional structure having one first joint of the prismatic type. Here, *unbounded* is used in a restricted sense, meaning much larger in one direction than the others. Moreover:
 - If one direction is required to be much larger than the others, then practical implementations of prismatic joints are available in the form of rails either overhead, thereby giving rise to *gantry* robots, or on the floor.
 - If two directions are required to be much larger than the other, then use a wheeled mobile robot carrying a manipulator on top. A famous realization of this concept is the National Aeronautical and Space Agency's (NASA) *Sojourner* used in the *Pathfinder* mission to Mars in 1997.
3. If axial symmetry is not required, but rather a workspace with various coplanar axes of symmetry, similar to those of regular polygons, use a parallel robot.

16.2.1 Reaching a Set of Goal Frames

Closely related to the problem of workspace specification is that of task specification. In mechanism design it is customary to specify a set of coordinate frames in space, and to design a mechanism with an a priori specified topology that can visit these frames. An order in which the frames must be reached may be given. In the event that not all of the frames are reachable, then one may seek a mechanism that

comes *closest*, in some suitable sense, to the specified frames. The literature on this classical mechanism design problem is vast [16.1, 11, 12] and the references cited therein. Some further remarks in connection with this goal-frame approach to robot dimensioning are noteworthy:

1. Reaching *exactly* the desired frames may not always be desired or possible: in some cases it is better to use an optimization approach that allows for solutions that will visit the desired poses within a minimum error (provided that an error norm can be suitably engineered, of course, as suggested in [16.13]).
2. It has been claimed [16.8] that interval analysis allows not only a discrete set of desired poses but also a full six-dimensional (6-D) workspace to be met while taking into account manufacturing errors.
3. The branching problem occurring in 1-DOF mechanisms may also occur in robot design: a design solution based on via points may indeed visit the prescribed poses, but not all of these may be reachable within the same assembly mode. This problem is exacerbated in the design of serial robots, as a 6-DOF, revolute-coupled robot may admit up to 16 distinct postures – branches – for one given EE pose [16.14, 15].
4. While a robot designed to visit a set of prescribed poses via its EE will be able to visit that set, we should not forget that the purpose of using robots is first and foremost to be able to perform not one single task, but rather a family of tasks. In this light, the set of poses for which a robot is designed might as well be a task that is *representative* of that family.

In connection with remark 4 above, we can cite the design or evaluation of SCARA systems. A SCARA system is a 4-DOF serial robot capable of tasks that lie within the *Schönflies* subgroup of the group of rigid-body displacements [16.16, 17], namely the set of three-dimensional (3-D) displacements augmented with a rotation about an axis of fixed direction. In these systems, the task at hand is given by two vertical segments joined by one horizontal segment. Moreover, the length of the vertical segments is 25.0 mm, that of the horizontal segment being 300.0 mm. While the EE is traversing the horizontal segment, moreover, it should rotate about a vertical axis through an angle of 180° . This task specification, which has been adopted by SCARA manufacturers, does not indicate how to negotiate the corners, which is left to the imagination of the robotics engineer.

Fig. 16.4 The workspace of the orthogonal robot of Fig. 16.3 (after [16.9])

16.2.2 Workspace Volume and Topology

Reachable and Dexterous Workspace

Beginning with the early work of Roth [16.18], there have been many studies on the relationship between manipulator kinematic geometry and its workspace. Most studies have focused on a classification of the workspace into two components, the *reachable* and the *dexterous* workspace [16.19]. Given a reference point P attached to a manipulator EE, such as the center of the spherical wrist, or a point on the EE, the reachable workspace is defined to be the set of points in physical space that can be reached by P. The dexterous workspace, on the other hand, is the set of points that can be reached by P with arbitrary EE orientations.

The early literature on workspace focuses on numerical and algebraic methods to characterize these workspaces. Reachable and dexterous workspaces have been analyzed using numerical techniques by Kumar and Waldron [16.19], Yang and Lee [16.20], and Tsai and Soni [16.21], among others. The advantage of these schemes over algebraic approaches is that kinematic constraints can be readily included. More-general design principles or insights, however, are more difficult to come by using these techniques. Among the algebraic approaches to workspace characterization, a topological analysis of robot workspace is given by Gupta and Roth [16.22] and Gupta [16.23]; here the concept of workspace holes and voids is defined, and conditions for their existence are identified. The shape of the reachable and dexterous workspaces is also analyzed as a function of P.

Further studies of workspace analysis were reported by Freudenstein and Primrose [16.24] and by Lin and Freudenstein [16.25], where precise relationships between kinematic and workspace parameters are developed, and a class of three-joint manipulators is optimized for workspace volume. A more general analysis of workspace optimization is given in Vijaykumar et al. [16.7]. Performance criteria for manipulators are defined here in terms of the dexterous workspace; given that a manipulator satisfies certain constraints on its Denavit–Hartenberg parameters, it is shown that the optimal six-revolute (6R) design is the elbow manipulator.

A typical design of robot regional architecture is of the *orthogonal type*, consisting of one revolute of the vertical axis and two revolutes of the horizontal axes, one of which intersects the vertical axis. Moreover, the most common architecture includes intermediate and distal links of identical lengths. The workspace of this architecture is thus a sphere of radius equal to twice that common link length. The volume of this workspace is thus determined by the length in question. As shown by Yoshikawa [16.26], the workspace of

the two-link planar manipulator defined by the last two links of the foregoing regional architecture is of maximum area for a prescribed reach and equal link lengths. As a result, the volume of the same regional architecture is similarly of maximum volume for a prescribed reach.

Differential–Geometric Workspace Characterization

Workspace can also be approached from a differential-geometric perspective, by regarding the configuration space of a robotic EE frame as a subset of the special Euclidean group SE(3). An important physical consideration in defining the workspace volume of spatial mechanisms is that it should not depend on the choice of fixed reference frame. Less obvious but just as important is the requirement that the volume should not depend on which point of the last link the EE frame is fixed to. This last condition has the following physical significance: if the EE were enlarged or shrunk, then the robot would have the same workspace volume. The workspace volume of a robot therefore depends only on the joint axes.

The workspace volume of a robot is defined by regarding SE(3) as a Riemannian manifold, so that the workspace volume is simply the volume of the image of the forward kinematic map f with respect to the volume form on SE(3). It is known that SE(3) has a bi-invariant volume form, that is, the notion of volume is invariant with respect to the choice of both the fixed (base) and moving (EE) frames – see, e.g., Loncaric [16.27]. Paden and Sastry [16.28] provide the following visualization for this volume form: Suppose an airplane is restricted to move within a cube of airspace of length 1 km on a side. At each point within this cube the airplane can point itself anywhere in a 4π solid angle and roll 2π about the direction it is pointing. The orientation volume at such an airplane is $4\pi \times 2\pi = 8\pi^2 \text{ rad}^3$. Multiplying by the positional volume one obtains $8\pi^2 \text{ rad}^3 \text{ km}^3$ for the volume of the free configuration space of the aircraft.

This depiction is the notion of workspace volume used for robots; it has the advantage of being able to trade off orientation freedom for positional freedom smoothly, unlike the popular notion of dexterous workspace. Note that the actual numerical value one obtains will depend on the choice of length scale for physical space; this in itself does not pose a serious problem for workspace volumes, as long as the same length scale is maintained when comparing different workspaces.

In [16.28] Paden and Sastry show that the optimal 6R manipulator that maximizes the workspace volume subject to a kinematic length constraint is the

elbow manipulator. This result is consistent with the earlier finding of Vijaykumar et al. [16.7], but the authors employ the geometric framework outlined above.

Moreover, the results are obtained without some of the a priori assumptions on the kinematic structure made by Vijaykumar.

16.3 Dexterity Indices

16.3.1 Local Dexterity for Open Chains

Dexterity can be defined as the ability to move and apply forces and torques in arbitrary directions with equal ease, the concept thus belonging to the realm of *kinetostatics*, which is the study of the interplay between *feasible twists* and *constraint wrenches* in multibody mechanical systems under *static conservative conditions*. Here, twist is the 6-D array of velocity variables of a rigid body, involving three components of a landmark-point velocity and three of angular velocity; wrench, in turn, is the 6-D array of static variables acting on a rigid body, three accounting for the resultant force applied at the same landmark point and three for the concomitant moment acting on the same body.

Salisbury and Craig [16.29] introduced the concept of dexterity when working on the design of articulated hands. At issue is the way in which input joint velocity errors propagate to the output velocities of each fingertip. To illustrate this concept, let $\mathbf{J}(\boldsymbol{\theta})$ denote the Jacobian of the forward kinematic map, i. e.,

$$\dot{\mathbf{t}} = \mathbf{J}(\boldsymbol{\theta})\dot{\boldsymbol{\theta}}, \quad (16.1)$$

in which $\boldsymbol{\theta}$ and $\dot{\boldsymbol{\theta}}$ denote the vectors of joint variables and joint rates, respectively, while \mathbf{t} is the EE twist, defined, in turn, as,

$$\mathbf{t} = \begin{pmatrix} \boldsymbol{\omega} \\ \dot{\mathbf{p}} \end{pmatrix}, \quad (16.2)$$

with $\boldsymbol{\omega}$ denoting the angular velocity of the EE and $\dot{\mathbf{p}}$ the velocity of the operation point P of the EE, at which the task is specified.

Assuming the Jacobian \mathbf{J} is $m \times n$, the singular value decomposition of \mathbf{J} can be expressed in the form

$$\mathbf{J} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T, \quad (16.3)$$

where \mathbf{U} and \mathbf{V} are respectively $m \times m$ and $n \times n$ unitary matrices, and $\boldsymbol{\Sigma}$ is a $m \times n$ matrix with zeros everywhere, except for its (i, i) entries, for $i = 1, \dots, n$ if $m > n$; otherwise, for $i = 1, \dots, m$. The non-zero elements are the (non-negative) singular values of \mathbf{J} . At nonsingular postures, the Jacobian is invertible and we can write

$$\dot{\boldsymbol{\theta}} = \mathbf{V}\boldsymbol{\Sigma}^{-1}\mathbf{U}^T\dot{\mathbf{t}}. \quad (16.4)$$

Furthermore, if we assume that all the components of both \mathbf{t} and $\dot{\boldsymbol{\theta}}$ have the same physical units, which is the case for purely positioning or purely orienting manipulators with only revolute joints, then we can take the Euclidean norm of both sides of (16.4), thereby obtaining

$$\|\dot{\boldsymbol{\theta}}\|^2 = \dot{\mathbf{t}}^T \mathbf{U} (\boldsymbol{\Sigma} \boldsymbol{\Sigma}^T)^{-1} \mathbf{U}^T \dot{\mathbf{t}}. \quad (16.5)$$

If we let $\mathbf{v} = \mathbf{U}^T \dot{\mathbf{t}}$ then the above expression for $\|\dot{\boldsymbol{\theta}}\|^2$ becomes

$$\mathbf{v}^T (\boldsymbol{\Sigma} \boldsymbol{\Sigma}^T)^{-1} \mathbf{v} = \|\dot{\boldsymbol{\theta}}\|^2. \quad (16.6)$$

Now, if the i -th component of \mathbf{v} is denoted by v_i , for $i = 1, \dots, n$, and we look at the mapping of the unit ball in \mathcal{J} , $\|\dot{\boldsymbol{\theta}}\|^2 = 1$, (16.6) leads to

$$\frac{v_1^2}{\sigma_1^2} + \frac{v_2^2}{\sigma_2^2} + \dots + \frac{v_n^2}{\sigma_n^2} = 1, \quad (16.7)$$

which is the canonical equation of an ellipsoid of semi-axes $\{\sigma_i\}_1^n$ in the \mathcal{G} -space, i. e., the space of Cartesian velocities, or twists of the EE. Notice that the ellipsoid in question takes its canonical form when represented in a coordinate frame of axes oriented in the directions of the eigenvectors of \mathbf{U} .

In summary the unit ball in joint space is mapped by the Jacobian-inverse \mathbf{J}^{-1} into an ellipsoid whose semi-axes are the singular values of \mathbf{J} . That is, \mathbf{J} *distorts* the unit ball in the joint-rate space into an ellipsoid in the EE-twist space. Hence, a measure of the quality of motion and force transmission of the robotic architecture from the joints to the EE is given by the above distortion; *the smaller the distortion, the higher the quality of the transmission*.

A measure of the Jacobian-induced distortion can thus be defined as the ratio of the largest σ_M to the smallest σ_m singular values of \mathbf{J} , which is nothing but the *condition number* κ_2 of \mathbf{J} based on the matrix 2-norm [16.30], i. e.,

$$\kappa_2 = \frac{\sigma_M}{\sigma_m}. \quad (16.8)$$

Actually, (16.8) is only one possibility of computing the condition number of \mathbf{J} , or of any $m \times n$ matrix

for that matter, and certainly not the most economical. Notice that this definition requires knowledge of the singular values of the Jacobian. However, computing the singular values of a matrix is as computationally intensive as computing eigenvalues, with the added cost of a polar decomposition [16.31]; the combined operation is slightly less expensive than the singular-value decomposition [16.32]. The most general definition of condition number, for $n \times n$ matrices, is [16.30]

$$\kappa(\mathbf{A}) = \|\mathbf{A}\| \|\mathbf{A}^{-1}\|. \quad (16.9)$$

The expression (16.8) is obtained when the matrix 2-norm is adopted in (16.9). The matrix 2-norm is defined as

$$\|\mathbf{A}\|_2 \equiv \max_i \{\sigma_i\}. \quad (16.10)$$

If, on the other hand, the *weighted matrix Frobenius norm* is adopted, which is defined as

$$\|\mathbf{A}\|_F \equiv \sqrt{\frac{1}{n} \text{tr}(\mathbf{A}\mathbf{A}^T)} \equiv \sqrt{\frac{1}{n} \text{tr}(\mathbf{A}^T\mathbf{A})}, \quad (16.11)$$

then, apparently, the computation of the singular values can be obviated. When the weight $1/n$ is omitted in the above definition, the standard Frobenius norm is obtained. Notice, however, that the weighted Frobenius norm is more significant in engineering, for it does not depend on the number of rows and columns of the matrix at hand. The weighted Frobenius norm, in fact, yields the root-mean-square (rms) value of the set of singular values.

The *Frobenius condition number* κ_F of the Jacobian \mathbf{J} , based on the matrix Frobenius norm, is then

$$\begin{aligned} \kappa_F(\mathbf{J}) &= \frac{1}{n} \sqrt{\text{tr}(\mathbf{J}\mathbf{J}^T)} \sqrt{\text{tr}[(\mathbf{J}\mathbf{J}^T)^{-1}]} \\ &= \frac{1}{n} \sqrt{\text{tr}(\mathbf{J}^T\mathbf{J})} \sqrt{\text{tr}[(\mathbf{J}^T\mathbf{J})^{-1}]}. \end{aligned} \quad (16.12)$$

One more important difference between the two forms of computing the matrix condition number is worth pointing out: $\kappa_2(\cdot)$ is not an *analytic function* of its matrix argument, while $\kappa_F(\cdot)$ is. Hence, the condition number based on the Frobenius norm can be applied to great advantage in robot architecture design, as $\kappa_F(\cdot)$ is differentiable and lends itself to gradient-dependent optimization methods, which are much faster than direct methods based only on function evaluations. In robot control, which requires real-time computations, $\kappa_F(\cdot)$ also offers practical advantages, for its computation obviates the knowledge of the singular values, only requiring a matrix inversion, which is a rather simple task.

The significance of the condition number in robot design and control can be best understood if we recall that the concept stems from numerical analysis in connection with the solution of the linear system of equations (16.1) for $\dot{\boldsymbol{\theta}}$. Given that \mathbf{J} is a function of both the architecture parameters and the posture variables $\boldsymbol{\theta}$, \mathbf{J} is known only to within the error with which those quantities are known. Further, let the architecture parameters, namely, the constant values in the Denavit–Hartenberg parameter list, be stored in an array \mathbf{p} . Both \mathbf{p} and $\boldsymbol{\theta}$ are known up to measurement errors $\delta\mathbf{p}$ and $\delta\boldsymbol{\theta}$, respectively. Moreover, the twist \mathbf{t} is input into the control software of the robot with an unavoidable error $\delta\mathbf{t}$.

In solving (16.1) for $\dot{\boldsymbol{\theta}}$ with floating-point arithmetic, the computed value is contaminated with a roundoff error $\delta\dot{\boldsymbol{\theta}}$. The *relative error* in the computed $\dot{\boldsymbol{\theta}}$ is related to the relative errors in the architecture parameters and posture variables by the relation [16.30]

$$\frac{\|\delta\dot{\boldsymbol{\theta}}\|}{\|\dot{\boldsymbol{\theta}}\|} \leq \kappa(\mathbf{J}) \left(\frac{\|\delta\mathbf{p}\|}{\|\mathbf{p}\|} + \frac{\|\delta\boldsymbol{\theta}\|}{\|\boldsymbol{\theta}\|} + \frac{\|\delta\mathbf{t}\|}{\|\mathbf{t}\|} \right), \quad (16.13)$$

where \mathbf{p} and $\boldsymbol{\theta}$ represent the (unknown) actual values of these vectors and \mathbf{t} the nominal value of the twist.

Nevertheless, the foregoing discussion applies to tasks involving either positioning or orientation, but not both. Most frequently, robotic tasks involve both positioning and orientation, which leads to Jacobian matrices with entries bearing disparate physical units, the consequence being that the Jacobian singular values have disparate units as well. Indeed, singular values associated with positioning bear units of length, whereas those associated with orientation are dimensionless. As a consequence, it is impossible to either order all singular values from smallest to largest or to add them all.

To cope with the issue of disparate units in the Jacobian entries, and to allow for the computation of the Jacobian condition number, the concept of *characteristic length* has been proposed [16.9]. The characteristic length L has been defined as the length by which the entries of the Jacobian with units of length are to be divided to render the Jacobian condition number a minimum at an optimum posture. This definition, while sound, lacks an immediate geometric interpretation, which has made its adoption in the robotics community difficult. In order to provide for a geometric interpretation, the concept of *homogeneous space* was recently introduced [16.33]. Using this concept, the robot architecture is designed in a *dimensionless space*, with points whose coordinates are dimensionless real numbers. In this way, the six Plücker coordinates [16.34] of lines are all dimensionless, and hence the columns

of the robot Jacobian matrix, comprising the Plücker coordinates of the revolute axes, are dimensionless as well. As a consequence, the Jacobian singular values are all dimensionless, and the Jacobian condition number can be defined. Once the robotic architecture has been designed for minimum condition number, under geometric constraints on link-length ratios and angles between neighboring revolute axes, for example, the maximum reach of the robot can be calculated. The maximum reach r will thus be a dimensionless quantity. When this quantity is compared with the prescribed maximum reach R , with units of length, the characteristic length is computed as the ratio $L = R/r$.

16.3.2 Dynamics-Based Local Performance Evaluation

Since motions are caused by forces and torques acting on rigid bodies, it seems reasonable to formulate performance indices that take into account the inertial properties of the mechanism. Asada [16.35] defines the *generalized-inertia ellipsoid* (GIE) as the ellipsoid described by the product $\mathbf{G} = \mathbf{J}^{-T} \mathbf{M} \mathbf{J}^{-1}$, where \mathbf{M} denotes the inertia matrix of the manipulator. This ellipsoid is that with semiaxes given by the singular values of the foregoing product. Yoshikawa [16.36], in turn, defines a corresponding dynamic manipulability measure as $\det[\mathbf{J} \mathbf{M}^{-1} (\mathbf{J} \mathbf{M}^{-1})^T]$. Physically these concepts represent two distinct phenomena. Suppose the robot is viewed as an input–output device, which, given a joint torque, produces an acceleration at the EE. Yoshikawa's index measures the uniformity of this torque–acceleration gain, whereas Asada's GIE characterizes the inverse of this gain. If a human operator were holding the EE and attempting to move it about, the GIE would measure the resistance of the robot to this EE motion.

Other measures that attempt to capture robot performance as a function of the dynamics can be cited: Voglewede and Ebert-Uphoff [16.37] propose performance indices based on joint stiffness and link inertia, with the aim of establishing a distance to singularity for any robot posture, while Bowling and Khatib [16.38] propose a general framework for capturing the dynamic capability of a general robot manipulator that includes the velocity and acceleration characteristics of the EE, taking into account factors such as torque and the velocity limits of the actuators.

16.3.3 Global Dexterity Measures

The above measures are local in the sense that they characterize the dexterity of a robot at a given posture. Local measures are useful for applications ranging

from redundancy resolution to workpiece positioning, but for design applications a global measure may be more desirable. One straightforward way of extending local measures to global ones is to integrate them over the allowable joint space. In [16.39] Gosselin and Angeles integrate the Jacobian condition number over the workspace to define a global measure, thereby producing a *global conditioning index*. For the simpler cases of planar positioning and spherical manipulators, the global conditioning index was found to coincide with its local counterpart.

16.3.4 Closed-Chain Dexterity Indices

The formulation of dexterity for closed chains presents a number of subtleties. The first obvious difference is that the joint configuration space of a closed chain will no longer be a flat space; in the general case it will be a curved multidimensional surface embedded in a higher-dimensional (typically flat) space. Also, dual to the open chain case, the forward kinematics for closed chains is generally more difficult to solve than the inverse kinematics, with the possibility of multiple solutions. Another important difference is that only a subset of the joints may be actuated, and that the number of actuated joints may even exceed the mechanism's kinematic degrees of freedom.

Several coordinate-based formulations for closed-chain dexterity have been proposed for specific mechanisms [16.40] and for cooperating robot systems whose joints are all assumed to be actuated [16.41, 42], at least some of which have led to apparently paradoxical results [16.43, 44]. Because of the nonlinear characteristics unique to closed-chain mechanisms discussed above, particular care must be exercised in formulating coordinate-based dexterity measures.

Another recent line of work has attempted a coordinate-invariant differential-geometric formulation of dexterity for closed chains. In this framework the joint and EE configuration spaces are regarded as Riemannian manifolds with an appropriate choice of Riemannian metric, with the choice of joint space metric reflecting the characteristics of the joint actuators. The previous notions of ellipsoid developed for serial chains can be extended to general closed chains, containing both passive and active joints, and possibly redundantly actuated [16.45, 46].

16.3.5 Alternative Dexterity-Like Measures

The various definitions of dexterity discussed above all refer to the same qualitative feature of the ability of a robot to move and apply forces in arbitrary directions. A different viewpoint is taken in the work of

Liégeois [16.47] and *Klein and Huang* [16.48], where dexterity is quantified in terms of joint-range availability. The driving motivation here lies in that most robots have joint limits; therefore, one should minimize the possibility of a joint reaching a stop.

Hollerbach [16.49] takes an alternative approach to designing a redundant seven revolute 7R manipulator, by considering: (a) elimination of internal singularities, (b) ability to avoid obstacles in the workspace, (c) the solvability of the kinematic equations, and (d) mechanical constructability. Based on these four criteria, he derived a particular 7R design with the morphology of the human arm, i. e., composed of two spherical joints defining the shoulder and the wrist plus an intermedi-

ate revolute playing the role of the elbow. Now, while a redundant architecture should remain fully capable of performing 6-DOF tasks upon locking one joint, the architecture reported in this reference may end up by losing this capability if the elbow joint is locked.

From a control perspective, *Spong* [16.50] shows that, if the inertia matrix of a manipulator has a vanishing Riemannian curvature, there exists a set of coordinates in which the equations of motion assume a particularly simple form. The curvature of the inertia matrix also reflects the sensitivity of the dynamics to certain robot parameters. Minimizing the curvature, therefore, is another possible criterion for robot design.

16.4 Other Performance Indices

16.4.1 Acceleration Radius

Another measure that attempts to capture the dynamic capabilities of a robotic manipulator is the *acceleration radius*. Initially proposed by *Graettinger and Krogh* in [16.51], the acceleration radius measures the minimum acceleration capability of the EE, in arbitrary directions, for the given torque bounds on the actuators. Specifically, given the dynamics equations for a serial chain in the form

$$\tau = \mathbf{M}(\theta)\ddot{\theta} + \mathbf{C}(\theta, \dot{\theta})\dot{\theta}, \quad (16.14)$$

in which \mathbf{M} is the robot *mass matrix* – also known as the *inertia matrix* – in *joint space*, and $\mathbf{C}(\theta, \dot{\theta})$ is the matrix mapping the joint-rate vector to the vector of Coriolis and centrifugal forces in the same space. Moreover, the actuators are assumed to have joint torque limits of the form

$$\tau_{\min} \leq \tau \leq \tau_{\max}, \quad (16.15)$$

where the lower and upper limits $\tau_{\min}, \tau_{\max} \in \mathbb{R}^n$ are constant or functions of the manipulator posture θ . The EE *twist rate*, denoted by \dot{t} , can be expressed as

$$\dot{t} = \mathbf{J}(\theta)\ddot{\theta} + \dot{\mathbf{J}}(\theta, \dot{\theta})\dot{\theta}, \quad (16.16)$$

where $\dot{\mathbf{J}}(\theta, \dot{\theta})$ is the Jacobian time-derivative. The Jacobian \mathbf{J} was introduced in (16.1).

Under the assumption that $\mathbf{J}(\theta)$ is nonsingular, one can write

$$\ddot{\theta} = \mathbf{J}(\theta)^{-1}\dot{t} - \mathbf{J}(\theta)^{-1}\dot{\mathbf{J}}(\theta, \dot{\theta})\dot{\theta}. \quad (16.17)$$

Substituting the above expression into the dynamic equations (16.14) leads to

$$\tau(\theta, t, \dot{t}) = \mathbf{M}'(\theta)\dot{t} + \mathbf{C}'(\theta, t)\dot{t}, \quad (16.18)$$

where

$$\mathbf{M}'(\theta) = \mathbf{M}(\theta)\mathbf{J}(\theta)^{-1}$$

$$\mathbf{C}'(\theta, t) = [\mathbf{C}(\theta, t) - \mathbf{M}(\theta)\mathbf{J}(\theta)^{-1}\dot{\mathbf{J}}(\theta, t)]\mathbf{J}^{-1}(\theta).$$

For a given state $(\theta, \dot{\theta})$, the linear torque bounds (16.15) now define a polytope in the twist-rate space. *Graettinger and Krogh* [16.51] define the acceleration radius to be the largest sphere centered at the origin that is contained in this polytope; its radius reflects the minimal guaranteed EE acceleration in arbitrary directions. This concept is applied to measure the EE acceleration capability of a manipulator, as well as to determine the actuator sizes for achieving a desired acceleration radius. *Bowling and Khatib* [16.38] generalize this concept to capture both force and acceleration capabilities of the EE, with a view to quantifying the worst-case dynamic performance capability of a manipulator.

16.4.2 Elastostatic Performance

Elastostatic performance refers to the robotic system's response to the applied load – force and moment, i. e., wrench – under static equilibrium. This response may be measured in terms of the *stiffness* of the manipulator, which determines the translation and angular deflections when the EE is subjected to an applied wrench.

Robot deflections have two sources: link and joint deflection. In the presence of long links, as in the space

robot Canadarm2, link compliance is a major source of deflection. However, in the majority of today's serial robots, the main source of deflection occurs at the joints.

In this chapter, we assume that the manipulator links are rigid, and model the joints as linearly elastic torsional springs. The more complex problem of link flexibility is studied in detail in Chap. 11. That is, for the elastostatic model we base our analysis on the assumption that, under a positioning task, the joints are locked at a certain posture θ_0 , while the EE is subject to a perturbation wrench Δw that is balanced by an elastic joint torque $\Delta \tau$. Under these conditions, $\Delta \theta$ and $\Delta \tau$ obey the well-known linear relation

$$\mathbf{K}\Delta\theta = \Delta\tau, \quad (16.19)$$

in which \mathbf{K} is the *stiffness matrix* in joint space at the given posture. Moreover, the matrix \mathbf{K} is diagonal, with its entries equal to the torsional stiffnesses of the corresponding joints, \mathbf{K} is therefore *posture independent*, i.e., constant throughout the whole robot workspace. Moreover, since all joints exhibit a finite, nonzero stiffness, \mathbf{K} is invertible, its inverse \mathbf{C} being termed the *compliance matrix*. We can thus express the inverse relation of (16.19) as

$$\Delta\theta = \mathbf{C}\Delta\tau. \quad (16.20)$$

It should be apparent that $\Delta\theta$ and $\Delta\tau$ have an *incremental* nature, for both are measured from the equilibrium posture, at which $\Delta\tau$ and $\Delta\theta$ vanish.

On the issue of stiffness matrix, *Griffis* and *Duffy* [16.52] proposed a mapping from an incremental rigid-body displacement Δx into an incremental wrench Δw that turned out to be nonsymmetric. The concept behind this mapping was formalized by *Howard*, *Zefran* and *Kumar* [16.53] by means of Lie algebra. However, in the foregoing papers, Δx and Δw turn out to be incompatible in the sense that their reciprocal product does not yield incremental work – the point at which Δx is defined is distinct from that at which Δw is applied. For this reason, the array representation of the same mapping cannot be, properly speaking, termed a stiffness matrix.

For a constant magnitude of $\Delta\tau$, the deflection attains its maximum value in the direction of the eigenvector associated with the maximum eigenvalue of \mathbf{C} or, equivalently, with the minimum eigenvalue of \mathbf{K} , denoted by κ_{\min} . In terms of elastostatic performance, we aim to (a) make the maximum deflection a minimum, i.e., we want to maximize κ_{\min} , and (b) make the magnitude of the deflection $\|\Delta\theta\|$ as insensitive as possible to changes in the direction of the applied load $\Delta\tau$.

This can be done by rendering κ_{\min} as close as possible to κ_{\max} . The first aim is associated with the stiffness constants, i.e., the higher the constants the lower the deflections. The later, however, is associated with the concept of isotropy, the ideal case being when all the eigenvalues of \mathbf{K} are identical, which means that \mathbf{K} is isotropic. Due to the *pyramidal effect* of serial robots, in which downstream motors carry their upstream counterparts, the joint stiffness is bound to be largest for the proximal joints. Hence an isotropic stiffness matrix is impossible for serial robots.

Notice that (16.19) and (16.20) may also be formulated in the task space, i.e.,

$$\mathbf{K}_C\Delta x = \Delta w, \quad (16.21)$$

where $\Delta x \equiv t\Delta t$, with Δt denoting a *small* time interval producing a correspondingly *small* change Δx in the pose of the EE. That is,

$$\Delta x = \mathbf{J}\dot{\theta}\Delta t = \mathbf{J}\Delta\theta, \quad (16.22)$$

which is a linear transformation of the joint-vector increment into the pose-increment vector. We show next that *the stiffness matrix is not frame invariant*. This means that, under the linear transformation from joint to Cartesian coordinates, *the stiffness matrix does not obey a similarity transformation*. For quick reference, we recall below the definition of similarity transformation: if $y = \mathbf{L}x$ is a linear transformation of \mathbb{R}^n into itself, and we introduce a change of vector basis, $x' = \mathbf{A}x$, $y' = \mathbf{A}y$, then \mathbf{L} changes to \mathbf{L}' , which is given by

$$\mathbf{L}' = \mathbf{A}\mathbf{L}\mathbf{A}^{-1}. \quad (16.23)$$

The above transformation of any vector of \mathbb{R}^n into another one of the same space, and of a matrix \mathbf{L} into \mathbf{L}' , as given by (16.23), is termed a *similarity transformation*. Notice that \mathbf{A} is guaranteed to be invertible, as it represents a change of coordinate frame.

Now, under the change of coordinates given by (16.22), (16.21) leads to

$$\mathbf{K}_C\mathbf{J}\Delta\theta = \mathbf{J}^{-T}\Delta\tau, \quad (16.24)$$

where we have used the kinetostatic relation [16.9]

$$\mathbf{J}^T\Delta w = \Delta\tau.$$

The exponent $-T$ denotes the transpose of the inverse or, equivalently, the inverse of the transpose. Upon multiplication of both sides of (16.24) by \mathbf{J}^T from the left, we end up with

$$\mathbf{J}^T\mathbf{K}_C\mathbf{J}\Delta\theta = \Delta\tau. \quad (16.25)$$

If we now compare (16.19) with (16.25), we can readily derive the relations between the stiffness matrix \mathbf{K} in joint space and the stiffness matrix \mathbf{K}_C in Cartesian space

$$\mathbf{K} = \mathbf{J}^T \mathbf{K}_C \mathbf{J} \quad \text{and} \quad \mathbf{K}_C = \mathbf{J}^{-T} \mathbf{K} \mathbf{J}^{-1}, \quad (16.26)$$

which apparently is not a similarity transformation between \mathbf{K} and \mathbf{K}_C . What this means is that the two matrices do not share the same set of eigenvalues and their eigenvectors are not related by the linear relation (16.22). As a matter of fact, if the robot is revolute-coupled, the entries of its stiffness matrix \mathbf{K} all have units of Nm, i. e., of *torsional stiffness*, while the entries of \mathbf{K}_C have disparate units. To show this, the Jacobian matrix, the inverse Jacobian and the two stiffness matrices are partitioned correspondingly into four 3×3 blocks, i. e., as

$$\mathbf{J} = \begin{pmatrix} \mathbf{J}_{11} & \mathbf{J}_{12} \\ \mathbf{J}_{21} & \mathbf{J}_{22} \end{pmatrix}, \quad \mathbf{J}^{-1} = \begin{pmatrix} \mathbf{J}'_{11} & \mathbf{J}'_{12} \\ \mathbf{J}'_{21} & \mathbf{J}'_{22} \end{pmatrix},$$

$$\mathbf{K} = \begin{pmatrix} \mathbf{K}_{11} & \mathbf{K}_{12} \\ \mathbf{K}_{12}^T & \mathbf{K}_{22} \end{pmatrix}, \quad \mathbf{K}_C = \begin{pmatrix} \mathbf{K}_{C11} & \mathbf{K}_{C12} \\ \mathbf{K}_{C12}^T & \mathbf{K}_{C22} \end{pmatrix}.$$

Furthermore, in light of the definition of the twist, (16.2), the two upper blocks of \mathbf{J} are dimensionless, while its two lower blocks have units of length [16.9]. As a consequence, the two left blocks of \mathbf{J}^{-1} are dimensionless, while its two right blocks have units of inverse length. Now, the blocks of \mathbf{K}_C are computed from the corresponding relation in (16.26), thereby obtaining

$$\begin{aligned} \mathbf{K}_{C11} &= \mathbf{J}_{11}^T (\mathbf{K}_{11} \mathbf{J}'_{11} + \mathbf{K}_{12} \mathbf{J}'_{21}) \\ &\quad + \mathbf{J}_{21}^T (\mathbf{K}_{12}^T \mathbf{J}'_{11} + \mathbf{K}_{22} \mathbf{J}'_{21}) \\ \mathbf{K}_{C12} &= \mathbf{J}_{11}^T (\mathbf{K}_{11} \mathbf{J}'_{12} + \mathbf{K}_{12} \mathbf{J}'_{22}) \\ &\quad + \mathbf{J}_{21}^T (\mathbf{K}_{12}^T \mathbf{J}'_{12} + \mathbf{K}_{22} \mathbf{J}'_{22}) \\ \mathbf{K}_{C21} &= \mathbf{K}_{C12}^T \\ \mathbf{K}_{C22} &= \mathbf{J}_{12}^T (\mathbf{K}_{11} \mathbf{J}'_{12} + \mathbf{K}_{12} \mathbf{J}'_{22}) \\ &\quad + \mathbf{J}_{22}^T (\mathbf{K}_{12}^T \mathbf{J}'_{12} + \mathbf{K}_{22} \mathbf{J}'_{22}). \end{aligned}$$

It is now apparent that: \mathbf{K}_{C11} has entries with units of Nm, i. e., of torsional stiffness; \mathbf{K}_{C12} and \mathbf{K}_{C21} have entries with units of N; and \mathbf{K}_{C22} has entries with units of N/m, i. e., of translational stiffness.

The outcome of the foregoing discussion is that a norm for \mathbf{K} is possible, but not one for \mathbf{K}_C , unless of course a characteristic length is introduced to render all the entries of \mathbf{K}_C dimensionally homogeneous. A norm of a matrix is useful as it indicates *how large* the entries of the matrix are. We would like to characterize how

stiff a robot is in both joint and Cartesian spaces. In joint space we could adopt any norm, but notice that the 2-norm, introduced in (16.8), would be misleading, as this norm would assign the value of the strongest joint to the overall robot stiffness. A more suitable norm would be the weighted Frobenius norm, introduced in (16.11), which would assign the rms value of the joint stiffnesses to the overall robot stiffness.

To design a robot optimally, we would therefore aim to maximize the Frobenius norm of its stiffness matrix in joint space, while observing constraints on the robot weight, as stiffer joints lead to heavier joints if the same material is used for all joints.

16.4.3 Elastodynamic Performance

For a general design problem, not only the kinetostatic and elastostatic performances, but also the elastodynamic performance have to be considered. In this regard, we introduce the assumptions of Sect. 16.4.2, with the added condition that inertia forces due to the link masses and moments of inertia are now taken into consideration.

The linearized model of a serial robot at the posture given by θ_0 , if we neglect damping, is

$$\mathbf{M} \Delta \ddot{\theta} + \mathbf{K} \Delta \theta = \Delta \tau, \quad (16.27)$$

in which \mathbf{M} is the $n \times n$ positive-definite mass matrix introduced in Sect. 16.4.1, while \mathbf{K} was defined in Sect. 16.4.2 as the $n \times n$ positive-definite stiffness matrix in joint space. Both \mathbf{K} and \mathbf{M} were defined in joint-space coordinates, $\Delta \theta$, representing the vector of joint-variable elastic displacements, as in Sect. 16.4.2. These displacements are produced when, as the joints are all locked at a value θ_0 and thereby become ideal linear springs, the robot is subject to a perturbation $\Delta \tau$, to nonzero initial conditions, or to a combination of both.

Under *free vibration*, i. e., under a motion of the system (16.27) caused by nonzero initial conditions and a zero excitation $\Delta \tau$, the foregoing equation can be solved for $\Delta \ddot{\theta}$

$$\Delta \ddot{\theta} = -\mathbf{D} \Delta \theta, \quad \mathbf{D} \equiv \mathbf{M}^{-1} \mathbf{K}, \quad (16.28)$$

in which the matrix \mathbf{D} is known as the *dynamic matrix*. This matrix determines the behavior of the system under consideration, as its eigenvalues are the *natural frequencies* of the system and its eigenvectors the *modal vectors*. Let $\{\omega_i\}_1^n$ and $\{f_i\}_1^n$ denote the sets of eigenvalues and the corresponding eigenvectors of \mathbf{D} , respectively. Under the initial conditions $[\Delta \theta(0), \Delta \dot{\theta}(0)]^T$, in which $\Delta \theta(0)$ is proportional to the i -th

eigenvector of \mathbf{D} and $\Delta\dot{\boldsymbol{\theta}}(0) = \mathbf{0}$, the ensuing motion is of the form $\Delta\boldsymbol{\theta}(t) = \Delta\boldsymbol{\theta}(0) \cos \omega_i t$ [16.54].

Furthermore, under the change of variables given by (16.22), the model (16.27) changes to

$$\mathbf{MJ}^{-1}\Delta\ddot{\mathbf{x}} + \mathbf{KJ}^{-1}\Delta\mathbf{x} = \mathbf{J}^T\Delta\mathbf{w}.$$

If we now multiply both sides of the above equation by \mathbf{J}^{-T} , we obtain the elastodynamic model (16.27) in Cartesian coordinates, namely

$$\mathbf{J}^{-T}\mathbf{MJ}^{-1}\Delta\ddot{\mathbf{x}} + \mathbf{J}^{-T}\mathbf{KJ}^{-1}\Delta\mathbf{x} = \Delta\mathbf{w},$$

in which the first matrix coefficient is the mass matrix \mathbf{M}_C in Cartesian coordinates, and the second is identified as \mathbf{K}_C , which was introduced in (16.26), i. e.,

$$\mathbf{M}_C \equiv \mathbf{J}^{-T}\mathbf{MJ}^{-1}. \quad (16.29)$$

The elastodynamic model in Cartesian coordinates thus takes the form

$$\mathbf{M}_C\Delta\ddot{\mathbf{x}} + \mathbf{K}_C\Delta\mathbf{x} = \Delta\mathbf{w}. \quad (16.30)$$

Again, by virtue of the transformation (16.29), it is apparent that the mass matrix, like its stiffness counterpart, is not invariant under a change of coordinates. Moreover, in a revolute-coupled robot, all the entries of \mathbf{M} have units of kg m^2 ; however, the entries of \mathbf{M}_C have disparate units. An analysis similar to that conducted in Sect. 16.4.2 for the stiffness matrix in Cartesian space reveals that, if \mathbf{M}_C is partitioned into four 3×3 blocks, then its upper-left block has units of moment of inertia, its lower-right block has units of mass, while its off-diagonal blocks have units of kg m .

Correspondingly, the dynamic matrix in Cartesian coordinates becomes

$$\mathbf{D}_C = \mathbf{M}_C^{-1}\mathbf{K}_C. \quad (16.31)$$

It is now a simple matter to prove that *the dynamic matrix is invariant under a change of coordinates*. Indeed, if we substitute transformations (16.26) and (16.29) into (16.31), we obtain

$$\mathbf{D}_C = \mathbf{JM}^{-1}\mathbf{J}^T\mathbf{J}^{-T}\mathbf{KJ}^{-1} = \mathbf{JM}^{-1}\mathbf{KJ}^{-1},$$

in which the dynamic matrix \mathbf{D} in joint coordinates can be readily identified in the final expression, and hence,

$$\mathbf{D}_C = \mathbf{JDJ}^{-1}, \quad (16.32)$$

which shows that \mathbf{D}_C is indeed a similarity transformation of \mathbf{D} . As a consequence, the dynamic matrix is indeed invariant under a change of coordinates, the two matrices thus sharing the same sets of eigenvalues, their eigenvectors being related by the same similarity transformation. That is, if the modal vectors in joint space – the eigenvectors of \mathbf{D} – are denoted by $\{\mathbf{f}_i\}_1^n$ and the modal vectors in Cartesian space are denoted by $\{\mathbf{g}_i\}_1^n$, then these two sets are related by

$$\mathbf{g}_i = \mathbf{J}\mathbf{f}_i, \quad i = 1, \dots, n. \quad (16.33)$$

Therefore, the natural frequencies of the elastodynamic model are the same, regardless of the space in which they are calculated, while their natural modes of vibration change under a similarity transformation.

Under an excitation of the form $\Delta\boldsymbol{\tau} = \boldsymbol{\theta}_0 \cos \omega t$ and zero initial conditions, the system is known to respond with a harmonic motion of frequency ω and magnitude that depends on both ω and the system *frequency spectrum* $\{\omega_i\}_1^n$ [16.54]. When ω equals one of the natural frequencies of the system, the response magnitude grows unbounded, a phenomenon known as *resonance*. For this reason, when designing a robot, it is imperative that its frequency spectrum does not involve any of the expected operation frequencies, which can be achieved by designing the robot with stiffness and mass matrices that yield a frequency spectrum outside of the frequency range of the operation conditions.

This design task is not straightforward. Indeed, while the stiffness matrix in joint space is constant, the mass matrix is posture dependent, i. e., $\mathbf{M} = \mathbf{M}(\boldsymbol{\theta})$. Because of this feature, the elastodynamic design of a robot is bound to be iterative: the design can be conducted for a *straw-man task*, i. e., a typical task in the target applications, thus defining a set of postures that lead in turn to a set of mass-matrix values. Then, the frequency spectrum for all these postures can be designed to lie above the frequency range of the straw-man task. Since the robot will eventually be commanded to execute other tasks than the straw-man task, simulation of alternative tasks is required to ensure that the design is safe from a resonance viewpoint.

16.5 Other Robot Types

Serial robots were fully developed, to a great extent, in the nineties, with **SCARA** systems capable of executing the standard manipulation task defined in Sect. 16.2.1 at

the rate of two cycles per second. Other, more sophisticated robots started appearing in the 1980s. Parallel robots were a natural extension of serial robots. They

presented new challenges to researchers, as their forward kinematics turned out to be quite more complex than the inverse kinematics of serial robots. Nowadays a few parallel and hybrid, i.e., serial-parallel robots, are found in applications in industry and other environments. A remarkable type of robot that emerged in the 1990s is *humanoids*, with their own design and control challenges. Flying and swimming robots are also developing fast. An outline of the design challenges brought about by these new types of robots is included below.

16.5.1 Robots Mounted on a Fixed Base: Parallel-Kinematics Machines

Under the umbrella *parallel-kinematics machines* (PKMs) are included robots comprising one base plate (BP), one moving plate (MP) and a set of limbs that couple the two. The earliest robot of this kind that attracted the attention of researchers is what is known as the *Gough–Stewart platform* (GSP), consisting of six limbs, each of the *SPU* type, where S, P and U stand for spherical, prismatic and universal joint, respectively. In fact, the first two belong to what is known as the six lower kinematic pairs [16.3] – the other four are R, H, C, and F, which are termed revolute, helical, cylindrical and planar pairs. The U joint is a concatenation of two R pairs with axes intersecting at right angles. Three of these six pairs, R, P and H, allow for 1-DOF motion between the two links that they couple; C allows for 2-DOF, while S and F allow for three. Each limb of the GSP thus allows for 6-DOF of the MP with respect to the BP.

The first and foremost task when designing a PKM is the choice of both the type and the number of limbs. As to the latter, it varies from two to six. Apparently, the DOF of a limb should be at least that of the PKM under design. The early PKMs studied, mainly in the 1980s, were invariably 6-DOF systems. Clavel [16.6] patented in 1990 what may be the first PKM with *reduced mobility*, i.e., with a $\text{DOF} = 3$, namely, a robot that allows pure translations of its MP. Spherical robots, like Gosselin's *Agile Eye* [16.55], are also of reduced mobility. Different from Clavel's Delta, all links of spherical linkages undergo spherical motion, rotating about the same point – the center of the sphere. Delta is supplied with links that undergo other motions than those of their MP, purely translational.

Other PKMs with reduced mobility appeared later, the best known being the H4, a 4-DOF system, patented in 2001 [16.56], and designed to implement Schönflies displacements (Sect. 16.2.1) of its MP. The foregoing patent came as a response to the need of ever faster pick-and-place robots for the packaging and the

electronics industry sectors, when it was apparent that the SCARA systems of the mid eighties had reached their limits because of their serial architecture. The H4 is manufactured by Adept Technology, Inc. under the name *Adept Quattro s650HS parallel robot*.

Motivated by the growing interest in fast robots with reduced mobility, two approaches to the design of PKMs with reduced mobility have been put forth: *screw theory* [16.57] and *group theory* [16.58]. By far, the most favored approach is the former, as screw theory is well established within the community of robot mechanicians. However, group theory offers features not found in screw theory, which is *local* in that its scope is limited to the *velocity level*. Group theory is applicable at the *displacement level*. What is at stake in this context is the *topology* of the robot, namely, the number of joints, links, limbs and the type of joints, what Hartenberg and Denavit [16.3] term the *number synthesis* and the *type synthesis*. These two activities correspond to the *qualitative synthesis* underlying the design process, which appears at the *conceptual* stage, as opposed to its *quantitative* counterpart; the latter appears at the *embodiment* and the *detail* stages of the design process [16.4]. Recently, a design paradigm based on the concept of complexity has been proposed [16.59], aimed at assessing the complexity of a linkage design variant based on the types of its joints.

As an extension of the Delta robot, ABB Robotics developed the *Flexpicker IRB360*, a hybrid system that comprises a Delta robot in series with a revolute joint at its MP that adds one fourth DOF to the purely translational motion of the Delta. The result is, thus, a hybrid Schönflies motion generator. ABB's robot is used in the food-processing industry.

A major bottleneck in the development of fast robots with reduced mobility is their structural stiffness. With the packaging and electronics industry requiring ever faster pick-and-place robots, capable of speeds greater than 3 cycles/s, high excitation frequencies are generated, which calls for structures much stiffer than those found in other applications areas. The ideal fast robot should have a parallel structure whose mass is negligible when compared to that of its payload and, at the same time, highly stiff. As the robots of interest are intended for the production of Schönflies displacements, any motion of their MP outside of this subgroup, namely, any tilt of the MP, is considered parasitical and should be of as small an amplitude as possible. This calls for a structure that exhibits a high rotational stiffness about any horizontal axis – under the assumption that the only rotational motion of the MP is about a vertical axis, which is usually the case. The challenge here is how to characterize this stiffness. A simple elastodynamic model of the structure is derived by assuming

that the limbs provide a linearly elastic suspension for the **MP**, which is assumed to be rigid. The structure can be regarded as a *generalized spring* [16.60], namely, a linearly elastic suspension that is fixed to one stationary base at one end and carries a moving rigid body at another end. Moreover, the suspension allows full 6-DOF *small-amplitude* displacements of the body. What is meant by the latter is rotations that entail a *small* angle – as small as to allow for an approximation of the type $\sin \theta \approx \theta$, with θ denoting the angle – and translations small with respect to the dimensions of the body. The motion of the **MP** can then be represented using a unit screw [16.57] multiplied by a *small* angle Θ . Under these conditions, the Cartesian stiffness matrix is of 6×6 , given that the screw is of dimension 6.

In characterizing the rotational stiffness of **PKMs**, one may think of resorting to the eigenvalues and eigenvectors of their stiffness matrix. There are some issues with this approach, however, for, in light of the different units of the four blocks of this matrix (Sect. 16.4.2) the eigenvalue problem associated with the matrix is meaningful only in a *generalized sense* [16.61], as explained presently. Let us recall the 6×6 Cartesian stiffness matrix \mathbf{K}_C , introduced in Sect. 16.4.2, and let us denote with \mathbf{k}_i its i -th eigenvector, a unit screw, and with κ_i its corresponding eigenvalue. The generalized eigenvalue problem associated with \mathbf{K}_C now can be stated as

$$\mathbf{K}_C \mathbf{k}_i = \kappa_i \mathbf{\Gamma} \mathbf{k}_i, \quad \mathbf{k}_i \equiv \begin{pmatrix} \mathbf{e}_i \\ \boldsymbol{\mu}_i \end{pmatrix}, \quad i = 1, \dots, 6, \quad (16.34)$$

in which \mathbf{e}_i is the unit vector denoting the direction of the axis of the i -th eigenscrew, $\boldsymbol{\mu}_i$ is the *moment* of the axis with respect to the origin and $\mathbf{\Gamma}$ is a permutation matrix that exchanges the top and the bottom blocks of a screw array, these two items being defined as

$$\mathbf{\Gamma} = \begin{pmatrix} \mathbf{O} & \mathbf{1} \\ \mathbf{1} & \mathbf{O} \end{pmatrix}, \quad \boldsymbol{\mu}_i = \mathbf{e}_i \times \mathbf{p}_i + p_i \mathbf{e}_i, \quad (16.35)$$

for $i = 1, \dots, 6$, \mathbf{O} and $\mathbf{1}$ denoting the 3×3 zero and identity matrices, respectively, while \mathbf{p}_i is the position vector of a point on the axis of the eigenscrew \mathbf{k}_i , while p_i is the *pitch* of \mathbf{k}_i . The moment of a line \mathcal{L} can be interpreted as that of a unit force whose line of action coincides with \mathcal{L} . The generalized eigenvalue problem of (16.34) now leads to

$$\mathbf{A}_i \mathbf{k}_i = \mathbf{0}, \quad \mathbf{A}_i = \begin{pmatrix} \mathbf{K}_{rr} & \mathbf{K}_{rt} - \kappa_i \mathbf{1} \\ \mathbf{K}_{rt}^T - \kappa_i \mathbf{1} & \mathbf{K}_{tt} \end{pmatrix}, \quad (16.36)$$

for $i = 1, \dots, 6$. In light of its definition, (16.34), $\mathbf{k}_i \neq \mathbf{0}$, and hence, (16.36) must admit a non-trivial solution,

which means that \mathbf{A}_i must be singular, thereby leading to the characteristic equation of \mathbf{K}_C , namely,

$$\det \begin{pmatrix} \mathbf{K}_{rr} & \mathbf{K}_{rt} - \kappa \mathbf{1} \\ \mathbf{K}_{rt}^T - \kappa \mathbf{1} & \mathbf{K}_{tt} \end{pmatrix} = 0, \quad (16.37)$$

where subscript i has been deleted from κ , for it is no longer needed. In light of the linear homogeneous form in κ of the foregoing 6×6 matrix, its determinant is a sextic polynomial in κ , the eigenvalue sought.

It is worth mentioning that the set of screws does not form, properly speaking, a vector space, for screws do not have a zero – they include a three-dimensional unit vector, which hence cannot vanish. By the same token, the set of screws does not admit a scalar product. Indeed, if two screw arrays are dot-multiplied, their product is meaningless, because it involves additions of quantities with disparate units. The pertinent concept is *reciprocity*: the *reciprocal product* of two unit screws, \mathbf{s}_1 and \mathbf{s}_2 is defined via matrix $\mathbf{\Gamma}$, introduced in (16.35), namely, $\mathbf{s}_1^T \mathbf{\Gamma} \mathbf{s}_2$, which rightfully has units of length. When the reciprocal product of two unit screws vanishes, the screws are said to be *reciprocal* to each other. The physical significance of the concept lies in that a unit screw multiplied by an amplitude F with units of force produces a *wrench*; one multiplied by an amplitude Ω with units of frequency yields a twist. If the wrench happens to be a pure force with line of action intersecting the axis of the twist – the case of a force applied at a door whose line of action intersects the axis of the hinges – then wrench and twist are reciprocal to each other in that the power developed by the wrench on the door undergoing a *feasible* twist is zero.

Now we have a result that parallels one applicable to symmetric $n \times n$ matrices:

Theorem 16.1

The eigenvalues of \mathbf{K} are real and the product $\kappa_i p_i$ is non-negative, while the eigenvectors $\{\mathbf{k}_i\}_1^6$ are mutually reciprocal.

its proof being found in [16.62] and [16.63].

Further, *decoupling* of the stiffness matrix means finding a new coordinate frame in which its two off-diagonal blocks vanish. Such a decoupling is not always possible, as shown below (See the *corrigenda* in [16.63]). It is known that the entries of the Cartesian stiffness matrix change according with a similarity transformation applicable to screws, which involves both a shift of origin and a change of the orientation of the original frame [16.64]. If the latter is labeled \mathcal{A} and the new frame \mathcal{B} , then \mathcal{A} is carried into \mathcal{B} by means of a shift of the origin given by vector \mathbf{d} and a rotation matrix \mathbf{Q} . In the sequel, the cross-product matrix

of a vector $\mathbf{v} \in \mathbb{R}^3$ will be needed. This is known to be a skew symmetric matrix \mathbf{V} with the property

$$\mathbf{V}\mathbf{x} \equiv \mathbf{v} \times \mathbf{x}, \quad \forall \mathbf{x} \in \mathbb{R}^3, \quad \mathbf{V} \equiv \text{CPM}(\mathbf{v}). \quad (16.38)$$

Now let $\mathbf{D} \equiv \text{CPM}(\mathbf{d})$, with \mathbf{d} defined above as the displacement that takes the origin of \mathcal{A} into that of \mathcal{B} . The components of a unit screw $\hat{\mathbf{s}}$ in \mathcal{B} change to those in \mathcal{A} according to the similarity transformation

$$[\hat{\mathbf{s}}]_{\mathcal{A}} = \mathbf{S}[\hat{\mathbf{s}}]_{\mathcal{B}}, \quad \mathbf{S} = \begin{pmatrix} \mathbf{Q} & \mathbf{O} \\ \mathbf{DQ} & \mathbf{Q} \end{pmatrix}, \quad (16.39)$$

the inverse of the 6×6 matrix \mathbf{S} being

$$\mathbf{S}^{-1} = \begin{pmatrix} \mathbf{Q}^T & \mathbf{O} \\ -\mathbf{Q}^T \mathbf{D} & \mathbf{Q}^T \end{pmatrix}. \quad (16.40)$$

Accordingly, the components of the stiffness matrix change, under the same similarity transformation, as [16.63]

$$[\mathbf{K}]_{\mathcal{A}} = \mathbf{\Gamma} \mathbf{S} \mathbf{\Gamma} [\mathbf{K}]_{\mathcal{B}} \mathbf{S}^{-1}, \quad (16.41)$$

which, were it not for matrix $\mathbf{\Gamma}$, looks like the similarity transformation of a $n \times n$ matrix. The presence of $\mathbf{\Gamma}$ is essential by virtue of the definition of the reciprocal product. Let, now,

$$[\mathbf{K}]_{\mathcal{A}} = \begin{pmatrix} \mathbf{K}'_{rr} & \mathbf{K}'_{rt} \\ (\mathbf{K}'_{rt})^T & \mathbf{K}'_{tt} \end{pmatrix}, \quad [\mathbf{K}]_{\mathcal{B}} = \begin{pmatrix} \mathbf{K}_{rr} & \mathbf{K}_{rt} \\ \mathbf{K}_{rt}^T & \mathbf{K}_{tt} \end{pmatrix}. \quad (16.42)$$

The distinct blocks of the two matrices are related by

$$\begin{aligned} \mathbf{K}'_{rr} &= \mathbf{Q}(\mathbf{K}_{rr} - \mathbf{K}_{rt}\mathbf{D})\mathbf{Q}^T + \mathbf{DQ}(\mathbf{K}_{rt}^T - \mathbf{K}_{tt}\mathbf{D})\mathbf{Q}^T \\ \mathbf{K}'_{rt} &= (\mathbf{QK}_{rt} + \mathbf{DQK}_{tt})\mathbf{Q}^T \\ \mathbf{K}'_{tt} &= \mathbf{QK}_{tt}\mathbf{Q}^T \end{aligned},$$

the decoupling condition following upon setting $\mathbf{K}'_{rt} = \mathbf{O}$, which leads to

$$\mathbf{Q}^T \mathbf{DQK}_{tt} = -\mathbf{K}_{rt}, \quad (16.43)$$

Now, since \mathbf{D} is a cross-product matrix, it is singular – its null space is spanned by vector \mathbf{d} . Based on Sylvester's Theorem [16.31], which states that the rank of the product of two matrices is at most the smaller of the matrix ranks, the left-hand side of (16.43) is singular, and hence, the right-hand side must also be singular, which is the decoupling condition sought. If block \mathbf{K}_{rt} is singular, then decoupling can be achieved by means of a shift of the origin, without changing the orientation of the frame, i. e., upon choosing $\mathbf{Q} = \mathbf{1}$ in (16.43). This result is summarized below:

Theorem 16.2

The stiffness matrix can be decoupled if and only if its off-diagonal block is singular. When this is the case, decoupling is achieved by a *similarity transformation* involving only a shift of origin.

The design criterion to apply here is, thus, to aim at a singular coupling block of the Cartesian stiffness matrix. This can be achieved by means of finite elements, but these work for one single robot posture. However, with the help of the concept of generalized spring, Taghvaiepour et al. [16.65] showed that it is possible to obtain the stiffness matrix of deformable links using that obtained with finite element analysis (FEA) at one particular posture, then transforming this matrix to obtain its counterpart at an alternate posture. The details on how to compute the displacement vector \mathbf{d} that helps decouple the stiffness matrix are given in [16.63].

Once the stiffness matrix is decoupled, the eigenvalues of the rotational and translational blocks can be readily found, and assess the performance of the robot from the stiffness viewpoint. As a matter of fact, in the presence of a decoupled matrix, the characteristic equation (16.37) reduces to

$$\det \begin{pmatrix} \mathbf{K}_{rr} & -\kappa \mathbf{1} \\ -\kappa \mathbf{1} & \mathbf{K}_{tt} \end{pmatrix} = 0, \quad (16.44)$$

Upon expansion, using the expression for the determinant of a block-matrix [16.66], the foregoing equation leads to

$$\det(\mathbf{K}_{rr})\det(\mathbf{K}_{tt} - \kappa^2 \mathbf{K}_{rr}^{-1}) = 0,$$

the characteristic equation in κ readily following

$$P(\kappa) \equiv \det(\mathbf{K}_{tt} - \kappa^2 \mathbf{K}_{rr}^{-1}) = 0, \quad (16.45)$$

which is apparently a cubic equation in κ^2 , the outcome being that the eigenvalues of the *decoupled* 6×6 Cartesian stiffness matrix occur in symmetric pairs, i. e., the six eigenscrews of the matrix occur in pairs of opposite chirality, while the absolute values of each pair are identical [16.62, 63].

16.5.2 Mobile Robots

Mobile robots bear an architecture similar to PKMs. Different from the latter, their limbs are not attached to a base plate, but free to move. In fact, their links proximal to the ground end by either feet or wheels, thereby leading to *wheeled* or, correspondingly, *legged* mobile robots. Mobile robots termed *hybrid* have been designed with a combination of wheeled and legged limbs. These robots take on various morphologies, as outlined below.

Wheeled Robots

The earliest of these robots were termed *autonomous guided vehicles (AGV)*. They were provided with a chassis and two motors, to implement the 2-DOF proper of any terrestrial vehicle equipped with conventional – as opposed to omnidirectional – wheels. These systems were capable of following a trajectory printed on the flat ground of a manufacturing facility. They had thus a rather limited mobility, but their load-carrying capacity was virtually unlimited.

Robots with conventional wheels are generally equipped with two pairs of pneumatic tires, that allow them to adapt themselves to irregular surfaces. Moreover, these robots can either bear steerable wheels, like MDA's *Rover Chassis Prototype (RCP)*, or change course by means of maneuvers involving different angular velocities of their tires mounted on axles fixed to the chassis, like the *Khepera* robot.

Extraterrestrial exploration has prompted the development of *rovers*, namely, wheeled robots intended for roaming on unstructured terrain, either soft, like the Moon's or Mars's regolith, or hard, like rocks. Design issues here pertain mainly to the wheels, as these must adapt themselves to a rich variety of conditions and terrain constitution. Rovers are currently designed to travel at very low speeds, sometimes of a few meters per day, the case of NASA's *Curiosity* (This rover landed on Mars on August 6, 2012.). The main issue here is for the wheels to provide enough traction and prevent spinning without advancing. The latter is guaranteed by the use of individual motors on each wheel. Traction is enhanced by means of *grousers* on the wheel periphery. *Curiosity* and *RCP* feature metal wheels with grousers.

Legged Robots
